A schematic diagram of a ramp-edge junction device structure is shown in Fig. 1. At first, a multilayer including a buffer layer (STO), a bottom electrode (LSMO), and a thick insulation layer (STO) was deposited *in situ* on LaAlO_3 substrate using pulsed laser deposition (PLD). The oxygen background pressure was 400 mTorr and the heater block temperature was 700 °C. The device was defined using conventional photolithography and the ramp edge was created by ion milling with Ar ions. The ramp-angle measured using atomic force microscope (AFM) after the Ar ion milling was 12°–14°. After removing the photoresist, a thin insulating barrier of STO and a top electrode of LSMO were deposited *in situ* under 400 mTorr oxygen and at 700 °C. The insulating barrier and the top electrode were patterned to form a junction and counter electrode as shown in Fig. 1. Finally, gold was sputtered for contact pads. The thicknesses of top and bottom electrodes are 900 and 1100 Å. The thickness of the insulating STO barrier is about 10–20 Å. The junction width is determined by the tap width as shown in Fig. 1(a) which was 5 μm. A detailed description of the ramp-edge device fabrication process can be found in an earlier publication.⁶

As-grown LSMO films under the above growth conditions have a Curie temperature, T_c , of 350 K and a metal-to-metal transition at the same temperature (LSMO has a paramagnetic metal-to-ferromagnetic metal transition near T_c).⁷ The resistive transitions of both top and bottom LSMO electrodes were measured after the device fabrication process and showed the same temperature dependence, suggesting

FIG. 1. Schematic diagram of a ramp-edge LSMO/STO/LSMO junction device. (a) Top view, (b) cross section of the junction area.

minimal damage from the patterning process. The JMR was measured with a four-terminal ac resistance bridge and a dc current source in fields up to ± 1 T in the temperature range of 16–300 K. The current was flowing across the insulating barrier layer similar to the current-perpendicular-to-plane (CPP) geometry in a trilayer sandwich junction.⁵ The magnetic field was applied in the plane either parallel or perpendicular to the current. No significant difference was observed in the field dependence of JMR. Also these junctions withstood temperature cycling and were stable in the ambient conditions.

The field dependent junction resistance, $R_j(H)$, and JMR, $\Delta R_j/R_j(1000 \text{ Oe})$ of a device at 15.7 K is shown in Fig. 2. JMR values as large as 30% are observed at low fields (between 180 and 220 Oe). The shape of JMR versus field is similar to that of metal-electrode-based tunnel junctions.¹ At high fields, the junction resistance is low because the magnetization in both electrodes is parallel. When H is between the coercive fields of the top and bottom electrodes (i.e., the electrode magnetization vectors are antiparallel), the junction resistance reaches a maximum value. Generally the JMR in-

FIG. 2. The junction resistance and magnetoresistance of the ramp-edge junction taken at 15.7 K. JMR is defined by $[(R_j(H) - R_j(1000 \text{ Oe})) / R_j(1000 \text{ Oe})]$. The arrows indicate the direction of magnetic field sweep.

FIG. 3. I - V characteristics of a junction at $T = 16.1$ K with $H = 5000$ (dotted line) and 200 Oe (solid line).

creases nearly linearly with decreasing temperature and saturates at values as large as 30% below 100 K. Large JMR ($> 10\%$) was observed in junctions with R_j ranging from 5 to 200 $\text{k}\Omega$.

The current-voltage (I - V) characteristics of a different junction measured at 16.1 K in $H = 5000$ (dotted line) and 200 Oe (solid line) are depicted in Fig. 3. As seen from Fig. 2, the magnetization in the electrodes is parallel (antiparallel) at $H = 5000$ Oe (200 Oe). At small bias voltages (± 0.1 V), the I - V characteristics show a linear behavior as expected for the tunneling junction with a high energy barrier.^{1,8} Since polycrystalline films⁹ and powder samples⁴ have the field dependent MR similar to Fig. 2 and linear I - V , there is a question whether these characteristics in the ramp-edge junctions are originated not from spin-dependent tunneling but from the granularity in electrodes. In some devices with a poor quality insulator barrier where the transport through microshorts is dominating, we observed a small JMR ($< 1\%$; similar to MR from epitaxial films) at low temperatures indicating the lack of polycrystalline and grain boundary effects across electrodes. This result establishes that the large JMR is from spin-dependent tunnelinglike transports. Unlike the conventional spin-dependent tunneling devices,¹ JMR in the ramp-edge devices does not depend on the dc bias voltage up to the measured range.

The high field JMR, $\Delta R_j(H)/R_j(1 \text{ T})$, at room temperature (solid line) and 20 K (dotted line) for a ramp-edge junc-

FIG. 4. The high field JMR, $\Delta R_j(H)/R_j(1 \text{ T})$, at room temperature (solid line) and 20 K (dotted line).

tion are presented in Fig. 4. As expected, the low field MR has a maximum in both cases suggesting that the spin-dependent tunneling can be observed even at room temperature. However, there are two questions arising from the results: (1) Why does R_j not saturate, but rather continues to decrease with increasing field up to ± 1 T; and (2) why is the JMR at room temperature so small compared with that at low temperature, even though the spin polarizability in LSMO changes less than 30% if estimated from the bulk magnetization?⁷ The similar results have been reported in the sandwich tunnel junctions⁵ and grain boundary devices¹⁰ using the doped manganites. The second question is especially important for device applications.

The value and the field dependence of JMR strongly depend on the magnetization process and the spin polarizability of the electrodes particularly near the junction. Even though the doped manganites do not have strong crystalline and magnetic anisotropies as a single crystal, magnetic anisotropies induced by the epitaxial growth and the film thickness^{11,12} have been observed in LSMO thin films. Domain pinning due to defects at the interfaces can also hamper the magnetization process. The magnetic anisotropy and domain pinning increase the field required to reach the saturation magnetization, hence, affecting JMR and its field dependence. There was a report on the reduced spin polarizability at the surface of a LSMO film,¹³ which can significantly reduce JMR at high temperatures. Also the surface degradation during the patterning process using ion milling can reduce the spin polarizability at the junction electrodes. The defect mediated scattering in the insulator and at the interfaces is another possible reason to reduce JMR.⁵

In summary, we have successfully fabricated LSMO/STO/LSMO junction devices using a ramp-edge geometry. A junction magnetoresistance of 30% in fields around 200 Oe was observed at $T=15.7$ K. A linear $I-V$ characteristic has been observed at low bias (± 0.1 V) and JMR does not

depend on the junction bias up to 0.1 V. The reduced JMR at high temperature and the field dependence of JMR at high fields can be caused by the magnetization process and the reduced spin polarizability at the junction electrodes.

We would like to thank Dr. M. E. Hawley for AFM support and Dr. Y. Gim for critical reading of the manuscript. This work was performed under the auspices of the United States Department of Energy.

The transport properties of metalorganic chemical vapor deposited films of lanthanum manganite grown on various substrates are investigated. The more disordered films show a magnetoresistance that is both large and relatively temperature independent over a wide temperature range. At low magnetic fields, a linear field dependence is observed and is attributed to spin-polarized intergrain tunneling. In addition, at low fields a hysteretic dependence of resistivity on the magnetic field has been observed. This effect has been attributed to the scattering of spin-polarized carriers at the grain boundary. © 1998 American Institute of Physics. [S0021-8979(98)18011-8]

INTRODUCTION

Because of their large magnetoresistance (MR), doped perovskite manganites show promise for magnetoresistive sensor applications. However, for a single crystal sample, the resistivity and MR are strongly temperature dependent, peaking sharply near the Curie temperature T_C , and the sensitivity to low fields remains small.¹ These characteristics limit the usefulness of the materials for technical applications. Yet in some recent experiments²⁻⁶ it has been shown that the existence of grain boundaries can drastically alter the temperature and low field behavior.

Our own efforts have focused on controlling the crystallite alignment (or texture) of the films via the choice of substrate; large lattice mismatches and other interface effects between the film and the substrate can lead to varying degrees of disorder in crystallite alignment. In this article, the temperature dependence and low field transport properties are examined for two highly disordered (low texture) $\text{La}_{0.59}\text{Ca}_{0.41}\text{MnO}_3$ films grown by liquid delivery metalorganic chemical vapor deposition (LD-MOCVD) on single crystal sapphire (SAP) and yttrium-stabilized zirconia (YSZ) substrates. Throughout, a comparison is drawn with a highly textured film of the same composition grown on LaAlO_3 (LAO).

EXPERIMENT

Details on the fabrication of the films by LD-MOCVD are reported elsewhere.⁷ The samples were not postannealed. The average orientation of the crystallites within the film was characterized with pole figures.

Van der Pauw⁸ transport measurements were performed in an ac four-probe configuration at magnetic fields up to 60 kOe. The three samples were mounted with the conducting plane parallel to the field (there is no demagnetization field in this configuration) and always measured simultaneously with a current of 0.1–1 μA . For large field sweeps, the rate was 2 kOe/min in both directions while for low field sweeps the rate was 200 Oe/min. In both cases, the measured field

values were corrected for sweep rate errors. For low field sweeps, the measurements were augmented with static field measurements in which the field was held constant for 10–30 min (relevant because of a time dependent hysteresis, discussed below).

Magnetic measurements were performed in a commercial superconducting quantum interference device (SQUID) magnetometer (Quantum Design). The samples were mounted with the film plane perpendicular to the field in order to measure the magnetization in emu/cm^3 directly without requiring knowledge of the film volume.

RESULTS

Pole figures were used to characterize the crystallite orientation of the samples; the results are shown in Fig. 1. They indicate that the LAO film is highly textured; the crystallites are well aligned with respect to the normal of the (001) surface as well as in the plane of the surface. The YSZ and

FIG. 1. Pole figures of the $\text{La}_{0.59}\text{Ca}_{0.41}\text{MnO}_3$ films grown on different substrates. The crystallites of the film on the (001) oriented LAO substrate (bottom) are very well aligned normal to the surface as well as within the surface plane. The crystallites on the (001) oriented YSZ (middle) are well aligned with their (110) direction normal to the surface, but randomly oriented otherwise. The least texture is developed in the film on the (0001) oriented SAP (top), faintly resembling the sixfold symmetry of the substrate.

FIG. 2. Zero-field resistivity vs temperature for the films grown on sapphire (SAP, top curve), yttrium-stabilized Zr_2O_3 (YSZ, middle curve), and LaAlO_3 (LAO, lower curve). The relative change of resistivity with varying temperature is small for the more disordered films.

SAP films are less textured with a preferentially oriented (011) surface direction. The crystallite alignment is more pronounced in the YSZ than in the SAP film.

The magnetization data in an applied magnetic field of 6500 Oe are comparable for all three samples, and reach a value of approximately 500 emu/cm^3 . This is below the maximum theoretical magnetization of about 570 emu/cm^3 . Magnetization versus temperature at 5 kOe (not shown) is similar for the three samples, as also found in Ref. 4. The data indicate $T_C \sim 230 \text{ K}$ for the films.

Figure 2 shows a plot of the logarithm of resistivity ρ versus temperature for the three films. Resistivity was calculated assuming an average thickness of $\sim 1000 \text{ \AA}$ for all three samples. The SAP and YSZ films have the same temperature dependence, with a difference only in magnitude. They are, however, quite different from the LAO film. The resistivity of the LAO film decreases by about two orders of magnitude between the temperature T_m of the resistivity peak and 50 K. While the SAP and YSZ films are much more resistive than the LAO film, they are much less sensitive to temperature, changing only by a factor of 3 in the same temperature range. The data resemble those³ for films grown on single crystal and polycrystalline SrTiO_3 .

A detailed study of the dependence of the resistivity ratio $\rho/\rho(H=0)$ on field and temperature is presented in Fig. 3 (the YSZ sample is not shown, but is similar to the SAP sample). For $T < T_m$, the YSZ and SAP films behave quite differently than the LAO film, featuring a steep low field slope that, around 2 kOe, breaks to a much more gradual dependence, nearly linear up to 30 kOe. In similar data for sintered bulk materials⁴ such features are attributed to spin-polarized intergrain tunneling. Close examination of our LAO sample also reveals these features, but at low temperatures (at 10 and 50 K), and over a much smaller resistivity scale. In fact, in the LAO sample the apparent contribution of intergrain tunneling leads to a more pronounced magnetoresistance at 50 K than at 100 K.

All three films also display a low field hysteretic resistivity peak, particularly prominent at low temperatures, as shown in Fig. 4 for $T = 10 \text{ K}$. Such hysteresis was not observed in Refs. 2–4 and 9. It has been demonstrated,^{5,6} however, that a low field hysteresis is a hallmark of grain boundary magnetoresistance caused by scattering of spin-polarized

FIG. 3. Resistivity ratio $\rho/\rho(H=0)$ vs magnetic field H (parallel to the film plane) for various temperatures. Data are shown for field sweeps in both directions. The top panels refer to the SAP sample; the bottom panels refer to the LAO sample. The left panels contain data for temperatures of 10, 50, 100, and 150 K. The right panels contain data for temperatures of 190, 230, and 300 K.

carriers at the interface. We emphasize that the relative magnitude of this effect remains much smaller for the LAO sample than for the YSZ and SAP samples, consistent with their differences in texture.

Finally, we observe a ubiquitous time-dependent hysteresis evident in fields as high as 60 kOe, common to some degree to all of our film samples (see, e.g., the high field, low

FIG. 4. The low field hysteresis in the resistivity ratio $\rho/\rho(H=0)$ vs magnetic field at 10 K for the SAP (top), YSZ (middle), and LAO (bottom) samples. Shown are data from a 0 to -2 kOe sweep (after first sweeping to 30 kOe and back), a 0 to 1 kOe sweep (after having continued the sweep from -2 to 30 kOe and then back to 0), and the return sweep to 0. Data were also acquired at static field points over long time periods (10–30 min) to verify the accuracy of the swept data.

temperature data in Fig. 3). This effect is clearly unconnected to the low field hysteresis (Fig. 4), which does not depend on time.

CONCLUSIONS

The substrate on which the $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ thin films are deposited strongly influences the film texture, which in turn has dramatic consequences on the film's magnetoresistive properties. A film grown on LAO is highly textured and shows many of the features observed in single crystals (such as resistivity and magnetoresistance sharply peaked near T_C). On the other hand, growths on YSZ and SAP substrates result in much more disordered films, and both the resistivity and MR remain substantial over a wider temperature range. Furthermore, the MR of the latter films show a large, linear field dependence at low fields up to 2 kOe, which has been attributed to spin-polarized intergrain tunneling. A low field hysteresis is also observed due to scattering of spin-polarized carriers at the interface. This effect was not observed in earlier studies of films on similar substrates.

The data show a clear correlation between transport properties and film texture. In other works,²⁻⁶ the transport properties characteristic of our disordered films have been attributed to grain boundary effects. These effects may be due to either (1) the number of grain boundaries (i.e., the size of the grains) or (2) the relative orientation of the grains.¹⁰ The pole figure measurements indicate that the grains are misaligned, so the latter mechanism should be prominent in the less textured films. However, we have been unable to

determine conclusively which of the two mechanisms contributes more to grain boundary effects in our samples.

The above observations point to the importance of film morphology in developing useful magnetoresistive devices from the lanthanum manganites.

The magnetoresistance and the magnetization of ceramic $\text{La}_{2/3}\text{A}_{1/3}\text{MnO}_3$ ($\text{A} = \text{Sr}, \text{Ca}$) oxides have been studied as a function of the grain size. It is found that these ceramics become magnetically harder when reducing the particle size exhibiting a large magnetic anisotropy that increases when reducing the grain size. In concomitance with this enhancement of the magnetic hardness, a gradual increase of the low-field magnetoresistance is also detected, signaling the relevance of the surface and interfaces contribution to the magnetic and transport properties. We suggest that both phenomena could be closely related and associated to the existence of some degree of spin disorder at the grain boundaries. We propose that these features are fingerprints of quenched spin disorder at interfaces that can be tuned through bandwidth modulation of the magnetic frustration. © 1998 American Institute of Physics. [S0021-8979(98)29211-5]

I. INTRODUCTION

The huge magnetoresistance (MR) of manganese perovskites (up to $10^7\%$) has a serious drawback on the need for large magnetic fields to obtain such large changes of the resistance. This fact was an important handicap since many of their potential applications require a good response in the low field regime. In this sense, the discovery of two well separated MR contributions in ceramic $\text{La}_{2/3}\text{A}_{1/3}\text{MnO}_3$ ($\text{A} = \text{Ca}, \text{Sr}$) samples, one attributed to an intrinsic intragranular component and the other to a nonintrinsic intergranular effects,² could be of a major importance for technological applications.

Even the actual mechanism laying behind the low field magnetoresistive response is still obscure, two different interpretations have been given, namely, spin-polarized intergrain tunnelling² and spin-dependent scattering at the grain boundaries.³ It is therefore evident that, whatever the mechanism, a strong influence of the surface magnetic disorder on the conduction process should be expected. The relevance of surface spin disorder in the later mechanism is evident by itself. On the other hand, according to the current understanding of the spin tunnelling mechanism, the MR should be proportional to the intergrain exchange coupling,⁴ that can be tuned by appropriate tailoring of both bulk and surface magnetic interactions.⁵⁻⁷ Therefore, reducing the particle size of the ceramics would imply an increase of the number of junctions and the low-field MR should be significantly enhanced. Nevertheless, since both the scattering³ and tunnelling⁴ models predict a quadratic dependence on the magnetization M [$\text{MR} \approx (M/M_s)^2$], it is not possible to distinguish between them on this aspect alone.

On the other hand, it has been shown that the degree of spin disorder can be controlled via the $\sigma^{1-x}(e_g)$ bandwidth, by the appropriate choice of the lanthanide^{6,7} or via the rela-

tive strength of the (F/AF) interactions by the choice of the alkaline earth.⁵ At the grain surface of a ceramic sample, charge carrier mobility should be severely dampened, the relative strength F/AF reduced, and therefore, the competition of interactions reinforced. At the same time, charge carriers in manganites are fully polarized and in a transport experiment, a current of carriers should travel from grain to grain. Thus, surface spin disorder should severely affect the intergrain resistivity, in a very sensitive way. In this article, we will explore the influence of both particle size and magnetic disorder on the low field magnetoresistive response of ceramic manganites.

II. EXPERIMENTAL AND RESULTS

Ceramic samples of $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ were prepared by conventional solid-state techniques in oxygen atmosphere,^{5,6} while $\text{La}_{2/3-x}\text{Y}_x\text{Ca}_{1/3}\text{MnO}_3$ ($x = 0-0.25$) samples were prepared by a sol-gel method.⁸ The particle size effects were studied in a series of four samples (A-D) of $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ with particle sizes of $A \approx 0.5-1 \mu\text{m}$, $B \approx 2-5 \mu\text{m}$, $C \approx 10-20 \mu\text{m}$, and $D \approx 50-100 \mu\text{m}$ prepared by using different methods (mechanical attrition and different sinterization temperatures) in order to control particle size.⁹ The influence of the magnetic disorder was explored in $\text{La}_{2/3-x}\text{Y}_x\text{Ca}_{1/3}\text{MnO}_3$ ($x = 0-0.25$) samples. Magnetization measurements were done using a superconducting quantum interference device (QD) (SQUID) system up to 5 T. Transport measurements were performed, using the standard four probe method, on samples of about $0.5 \times 1 \times 5 \text{ mm}^3$ with the current applied perpendicular to the magnetic field.

In Fig. 1 we show the $\rho(T)$ curves for samples A-D. The electrical resistivity has essentially the very same form and steadily increases, in all the temperature range, from sample D to A reflecting grain size reduction and degradation of the grain connectivity. A sort of maximum of the resistivity exists at $T \approx 365 \text{ K}$ for all the samples, thus showing that the oxygen stoichiometry is essentially the same.

^{a)}Electronic mail: Ben.Martinez@icmab.es

FIG. 1. Thermal dependence of the electrical resistivity of the $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ samples as a function of the particle size.

As already observed in ceramic samples,² the magnetoresistance (MR) of samples A–D, as a function of field, displays two well defined regimes.⁹ In the low-field regime extending only a few kOe, a sharp decrease is found, with variations of MR up to 30% at low temperatures, but decreasing when T increases. On the contrary, in the high field regime the variation of MR is almost linear with a slope $S = dR(H)/dH$ very much smaller than for low fields.

The low field MR may be evaluated by extrapolating back to $H=0$ the almost linear behavior of the normalized resistance $[R(H)/R(0)]$ observed above 5 kOe. Subtracting the intercept with the y axis from 1 we have the variation of the MR in the low field regime, the so-called low field magnetoresistance (LFMR) depicted in Fig. 2. The key point in this figure is that LFMR not only decreases with T but, also clearly depends on the particle size, becoming smaller as the particle size increases. It is also worth mentioning that the MR does not show the expected quadratic dependence on the magnetization at any temperature (see inset of Fig. 2).

Our results also show that the slope $S = dR(H)/dH$ of the high field linear portion of $R(H)$ becomes progressively reduced when increasing the particle size.⁹ Thus, even the high field region of $R(H)$ is affected by grain boundary effects. Nevertheless, a significant difference does exist be-

FIG. 2. Low-field magnetoresistance as defined in the text vs temperature as a function of the particle size (A=0.5–1 μm , B=2–5 μm , C=10–20 μm , and D=50–100 μm .) Inset: MR vs normalized magnetization, the absence of the expected quadratic dependence on M/M_s is evidenced.

tween the low and the high field regimes: whereas in the first case, the normalized LFMR, strongly depends on the particle size, the high field magnetoresistance dependence is very smooth.

On the other hand, the isothermal field dependence of the magnetization in ferromagnets can be described in terms of the so-called “law of approximation to saturation” (LAS):

$$M(H) = M_s [1 - a/H - b/H^2] + \chi_d H, \quad (1)$$

where M_s is the saturation magnetization, χ_d is the high field differential susceptibility, and a and b are fitting parameters. In order to get an estimate of the magnetic anisotropy energy in these samples we assume, in a first approximation, the expression of K_1 for uniaxial systems:

$$K_1 = [(105/8)bM_s^2]^{1/2}. \quad (2)$$

The obtained values of K_1 are around 10^7 erg/cm³. These values of the magnetic anisotropy are surprisingly large for a transition metal oxide and raises several questions about its origin. Nevertheless, they should be considered just as an upper limit for the magnetic anisotropy since, at the maximum field applied (55 kOe) samples may be far from saturation and other contributions (canting, frustration, etc.) may affect the values determined in this way. In any case, it is evident that decreasing the particles size implies an increment of the magnetic hardness that is reflected also in the increase of the LFMR. Whether the origin of this hardness is an increase of the surface anisotropy or an increase of the magnetic frustration is still an open question. We think that it may be closely related with the existence of a magnetically disordered surface layer, as already observed in magnetic nanoparticles,¹⁰ whose contribution increases as particle size decreases and is specially relevant for transport experiments since electrons have to cross through this surface layer from one grain to another.

In order to check this idea we have modified the spin disorder in ceramic samples of $\text{La}_{2/3-x}\text{Y}_x\text{Ca}_{1/3}\text{MnO}_3$ ($x=0-0.25$), with essentially the same particle size, by changing the Y content. As already mentioned in the introduction, the competition between F and AF interactions can be tuned via the $\sigma^{1-x}(e_g)$ bandwidth,^{6,7} or by the choice of the alkaline earth.⁵

The $\rho(H)$ and $M(H)$ loops for samples with $x=0, 0.15$, and 0.25 are shown in Fig. 3. It is found that both coercive fields, H_c , and anisotropy fields, H_a , increase gradually with x showing no other contributions to the irreversibility than those coming from domain rotation. Nevertheless, (ZFC-FC) measurements at high fields do show irreversible behavior below about 40 K (see Fig. 4) and, as expected, the irreversibility becomes broader as x increases. The existence of magnetic irreversibility at such high fields is attributed to the freezing of a part of the spin system into a metastable spin-glass-like state, in close similarity with what is observed in magnetic nanoparticles.¹⁰

As shown in Fig. 3, the electrical resistivity displays strongly enhanced hysteresis as compared to the magnetization and it is more evident as x increases. Notice, for in-

FIG. 3. $R(H)$ loops for the three samples of $\text{La}_{2/3-x}\text{Y}_x\text{Ca}_{1/3}\text{MnO}_3$ as a function of the doping rate ($x=0, 0.15$, and 0.25). Inset: Detail of the positive quadrant of the hysteresis loops for the same three samples.

stance, that for $x=0.25$, at 5 K, $\rho(H)$ is irreversible up to 55 kOe whereas the $M(H)$ is closed at about 2 kOe.

In short, irreversibility in the resistivity appears to be more prominent than in the magnetization. This observation is extremely significant because it clearly shows that even if a small fraction of the spins are frozen in a disordered configuration [the $M(H)$ loops are closed], the resistivity is still hysteretic. The obvious explanation of this remarkable result is that electrical resistivity measurements sense the surface spin state at the grain boundaries. It is thus clear that any effect modifying the surface magnetization should change $\Delta\rho$. Therefore, the irreversibility in $\rho(T, H)$ reveals a quenched surface spin disorder. It also means that the surface glassiness displays significant magnetoresistance. It is clear that in our micrometric particles, the surface spins contribution to the magnetization should be necessarily only a minor fraction of the bulk magnetization. For instance, from the $\Delta M(10 \text{ K}, 5 \text{ kOe})$ value one can estimate a nonmagnetic layer of about 10 nm, that is only of about 1% of the particle radius.

FIG. 4. ZFC-FC curves of both magnetization and resistance for the sample of $\text{La}_{2/3-x}\text{Y}_x\text{Ca}_{1/3}\text{MnO}_3$ with $x=0.25$ in a field of 40 kOe. Inset: Detail of the low temperature region showing the irreversibility in both $M(T)$ and $R(T)$.

The resistivity measured after ZFC-FC processes also displays low-temperature hysteretic behavior and, as expected, the FC resistivity is always lower than the ZFC one. In Fig. 4 we include the $\rho(T, 50 \text{ kOe})$ data for the $x=0.25$ sample. We note again the more pronounced irreversible character $\rho(T)$ when compared to $M(T)$: i.e., for $x=0.25$, the difference in $\rho(T)$ ZFC/FC is of about 20% while $\Delta M \approx 3\%$. Therefore, the available experimental data, particularly the observation of open hysteresis loops $\rho(H)$ up to fields well above (at least one order of magnitude) H_a can be well understood as a result of the existence of a significant spin disorder at the grain boundaries. The persistence of hysteresis on the resistivity when magnetization loops are almost reversible is a key observation which, essentially reveals the surface nature of the spin disorder. This hysteresis is more pronounced in the Y rich samples; an effect which is consistent with an enhanced magnetic frustration and the softer interatomic magnetic coupling.^{6,7} The observation of higher coercive fields for $x=0.25$ than for $x=0$ (Fig. 3) also fits into this picture.

III. CONCLUSION

In summary, we have shown that the MR of ceramic samples displays a clear dependence on the particle size specially in the low field regime. The magnetic behavior gives clues in the sense that the system becomes magnetically harder as particle size decreases, whether it is due to an increase of magnetic surface anisotropy or an increase of the magnetic frustration is still an open question. In this sense, we have shown that spin disorder seems to be increased at grain surface. Low-field magnetoresistance, could thus originate from the field suppressed magnetic disorder at the particle surface layer. The relevance of these observations for the spin polarized devices, where magnetic and electrical interfaces are at the heart, is thus as clear as polarization and can be seriously reduced.

We have developed a magnetic imaging scheme using the magnetoresistive spin valve head in a dc bias mode as a sensing element. By scanning the head in contact with the sample we obtain a submicron spatial resolution map of the normal component of the magnetic field in the temperature range 4.2–300 K. The writing element of the sensor can be used to alter the local magnetic structure in a controlled way. This technique was applied to image the magnetic domain structure down to 77 K in patterned thin films of $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$, known for their colossal magnetoresistance. A reorientation of single or multiple domains in the films was accomplished by applying a local magnetic field with the writing element, while the effect on magnetotransport was monitored with the simultaneous measurement of current–voltage characteristics. © 1998 American Institute of Physics. [S0021-8979(98)27911-4]

The drive toward high areal densities in magnetic recording has led to significant advances in developing high spatial resolution read/write magnetic sensors. Presently, the state-of-the-art sensors in the recording industry are magnetoresistive spin valve heads (MRSVs).¹ With excellent (submicron) spatial resolution (at least in one direction) and high field sensitivity of nearly $30 \mu\text{V/G}$, these sensors deliver a capability beyond the magnetic storage media, for which they were originally designed. Integrated into a suitable scanning system, they offer a uniquely robust scheme to image surface magnetic fields on a submicron scale in materials of both scientific and technological interest.

The past several years have witnessed growing development and use of a variety of magnetic imaging techniques. Among these techniques are magnetic force microscopy (MFM),² scanning superconducting quantum interference device (SQUID) microscopy,³ Lorentz transmission electron microscopy (LTEM),⁴ Kerr microscopy,⁵ scanning micro-Hall probe microscopy (SHPM),⁶ and others. All of these techniques record the magnetic structure at the surface of the material by sensing a vertical component of the surface stray magnetic fields. The techniques vary in their limits of applicability. A SQUID microscope, for example, has the highest field sensitivity. It can resolve $10^{-6} \Phi_0/\text{Hz}^{1/2}$ at a noise level of $4 \times 10^{-7} \text{ G/Hz}^{1/2}$. However, since it uses a superconducting device, the temperature window is limited to below the transition temperature T_c and the spatial resolution is at best a few microns, limited by its pickup loop area. MFM, on the other hand, has an excellent spatial resolution ($\sim 50 \text{ nm}$), but it requires a separate knowledge of surface topography and is difficult to quantify since it responds to field gradients. LTEM has been used to image magnetic domain boundaries with remarkable detail, but at a price of hardware complexity and cost.

We set out to develop a simple and robust magnetic sensing scheme using the leading edge technology magnetoresistive spin valve heads—the scheme closest to the scan-

ning Hall technique, but less costly and with less material complexity.⁶ The unique feature of MRSV heads—in addition to their noninvasive “read” function—is their “write” capability. They can be used to locally apply a field and thus provides an additional tool to control and probe a local magnetic environment on the surface. MR heads were used previously to image and manipulate bits on magnetic storage disks⁷ using ac mechanical modulation and in dc mode to image and record bits on magnetic disks and image magneto-optic and perpendicular media, magnetic tape, and magnetic particles at room temperature.⁸ The sensitivity of our MRSVs allows us to use them in a dc mode and also at cryogenic temperatures, thus expanding the applicability range.

The spin valve is a layered structure which consists of magnetic layers weakly coupled across a thin copper layer. While the magnetization in one magnetic (pinned) layer is fixed, the other (free) layer can change its magnetization depending on the local magnetic environment. The field sensitive component of the resistance of the structure depends on the cosine of the relative angle between the magnetization vectors in the two magnetic films, making the spin valves attractive as simple and efficient sensors for low field applications.¹ The technique we describe involves raster scanning a MRSV sensor in physical contact with the imaged surface. A schematic of the instrument is shown in Fig. 1. The MRSV head is attached to a flexible cantilever, which adjusts to variations in surface topography. The sample is mounted on a high-precision, x – y – z positioning stage driven by a mechanical micromotor. The x – y component of the stage is used for raster scanning. Approach to the sample is made by using a micrometer screw, while at the same time monitoring the output signal of the device. The scan dimensions range from 20 to $400 \mu\text{m}$ at 77 K, with a nominal scan step of 500 nm. The action of the mechanical motor (with a $0.5 \mu\text{m}$ step) is further reduced with a lever.³ The spatial resolution of the images is limited by the size of the gap between the shields ($0.25 \mu\text{m}$ in our case). A dc current bias in the range of 3–4.5 mA is supplied to the MRSV element

FIG. 1. A schematic of the experimental setup with an expanded view of the inductive coil of the “write” element and the outer shield in the upper left corner. The MR head (not drawn to scale) is scanned in contact with the sample. The “read” element is $2\ \mu\text{m}$ behind the “write” element.

by a constant current source and the magnetoresistive response is recorded in a Wheatstone bridge configuration. The sensitivity at these current levels is $\sim 30\ \mu\text{V/G}$. The “write” function of the head is accomplished with currents of ± 20 – $40\ \text{mA}$ through the “write” element, corresponding to fields up to $80\ \text{G}$ at the surface. The system is configured so that the magnetic surface imaging can be recorded simultaneously with the dynamic resistance (dV/dI) and the current–voltage (I – V) characteristics of the sample under study using a standard ac modulation technique. The entire stage is placed in a liquid helium cryostat where, by means of helium exchange gas, the temperature is controlled in the range 4.2 – $300\ \text{K}$.

We demonstrate the capability of this technique by using it in a study of colossal MR (CMR) manganite perovskite thin films⁹ grown on periodically grooved single crystal, a (100) oriented single crystal, and a polycrystalline SrTiO_3 substrate as described previously.¹⁰ CMR materials have received a great deal of attention because of their potential for sensor and memory applications.^{10–14} A large low-field MR component has been observed in polycrystalline thin films and bulk manganite samples.^{10,11} While the exact mechanism for this low-field MR is not yet completely understood (magnetotunneling^{11,14} versus spin scattering at the grain boundaries¹⁰), the degree of alignment of the magnetization in adjacent grains is crucial for the magnetotransport. By using the read/write MR head we can directly probe the effect of changes in the intragranular domain structure on magnetotransport.

An illustrative example of a MRSV image is shown in Fig. 2. This image is of a $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ film deposited on a patterned substrate with regularly spaced grooves. The thickness of the magnetic layer follows the morphology of the corrugated surface. The domain structure is controlled by the step-edge weak links appearing as a result of sharp steps in the topography of the substrate. The spatial periodicity here is about $5\ \mu\text{m}$, but we can resolve single magnetic domains of submicron size, well visible along the washboard pattern. This image was obtained after the film was cooled down to $77\ \text{K}$ in the remnant field.

The “write” capability of the MRSV element is illus-

FIG. 2. An image of a $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ film deposited on a periodically grooved substrate. The full gray scale corresponds to a field variation of $38\ \text{G}$. Black corresponds to a negative field (\downarrow) and white to positive field (\uparrow).

trated in Fig. 3, which shows an image of a $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ epitaxial film deposited on a 24° bicrystal SrTiO_3 substrate. Cooling the sample down to $77\ \text{K}$ in an in-plane homogeneous external field of $100\ \text{G}$ [above the coercive field $H_c(77\ \text{K})=30\ \text{Oe}$] allows us to image the bicrystalline grain boundary because the local disorder along the boundary nucleates a domain structure on the scale of the physical width of the boundary ($\sim 10\ \text{\AA}$). The magnetic width of the boundary is $\sim 2\ \mu\text{m}$, wider due to spreading of the return field lines at the surface. We search for the anisotropy induced effects by writing five domains, two on each side of the boundary and one directly on the boundary. The domains are nucleated by a $30\ \text{mA}$ pulse through the inductive coil of the “write” element. The images of the domains in Fig. 3 show vertical (\uparrow and \downarrow) components of the field at the edges of the domains. The effect of the crystallographic mismatch produces domains of different shapes on the two sides of the boundary. This effect can be imaged due to the elongated shape of the “write” element.

Now we illustrate the joint “read,” “write,” and magnetotransport measurement capabilities of our MRSV microscope using patterned polycrystalline manganite films, which exhibit a low-field MR effect.¹⁰ The task here is to switch the individual grains in the “write” mode, to image them in the “read” mode, and to correlate these images with the magnetotransport across the grain boundaries. We pattern a $10\ \mu\text{m}$ wide bridge structure in films with an average grain size of $\sim 14\ \mu\text{m}$. Thus, we have a single grain across the bridge width and a few grains along its length. The image in Fig.

FIG. 3. Domains written on a $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ epitaxial film deposited on a bicrystal substrate. The grain boundary appears as a faint line. The black and white spots correspond to the poles of the written domains.

FIG. 4. Images of $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ polycrystalline films (a) before and (b) after using the “write” element over the center of the bridge. (c) The difference between the images (a) and (b) shows the switched domains only.

4(a) shows well resolved individual grains with randomly oriented in-plane magnetization. Curve 2 in Fig. 5 shows simultaneously obtained dV/dI of this domain configuration, measured across the entire length of the bridge. We modify the domain configuration by writing with a 40 mA pulse at the center of the bridge [Fig. 4(b)]. The difference image in Fig. 4(c) clearly indicates the local action of the “write” element—only domains in the center of the bridge are altered, and the corresponding dV/dI vs V (curve 3) reflects this switch. Switching different grains along the bridge length produces a variety of dV/dI 's (curves 1, 4, and 5), depending on the local grain configuration and on the writing current. The curves represent averaging over several grains on the bridge. The resistance change across the grain boundaries, produced by the rotation of magnetic moment in adjacent grains, is about $50\ \Omega$. An indirect indication of this process was reported in Refs. 10, 12, and 13. The parabolic shape of dV/dI vs V in Fig. 5 can be produced either by tunneling¹⁵ or by spin scattering¹⁰ at the boundary. A detailed temperature dependence of the transport across a single grain will enable to distinguish between the two processes.

FIG. 5. Dynamic resistivity vs voltage curves of a polycrystalline bridge with different domain configurations. Parabolic fits to the data are shown as solid lines. Curves 2 and 3 correspond to the configuration imaged in Figs. 4(a) and 4(b), respectively.

Magnetic anisotropy of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ thin films and single crystals has been measured using vibrating sample and torque magnetometry. The magnetic anisotropy of thin films is dominated by strain anisotropy due to the lattice mismatch between the film and SrTiO_3 substrate. The two and fourfold symmetries in the (110) and (001) films, respectively, can only be explained by stress anisotropy contributions ($K_{\text{stress}} \sim 8.4 \times 10^4 \text{ ergs/cm}^3$). Magnetic anisotropy of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ single crystals, subject to no external stress, reveals a uniaxial anisotropy in the (100) plane of $K_1 \sim 1.8 \times 10^4 \text{ ergs/cm}^3$ that can be attributed to magnetocrystalline effects. © 1998 American Institute of Physics. [S0021-8979(98)20511-1]

The doped manganites materials $\text{RE}_{1-x}\text{AE}_x\text{MnO}_3$ (for trivalent rare earth ions RE and divalent alkaline earth ions AE) have received much interest due to the “colossal” changes in resistance in response to an applied field.¹⁻⁵ Bulk studies of the manganite materials have revealed dramatic changes in magnetic properties, including magnetoresistance and Curie temperature, in response to lattice distortions imposed by chemical or hydrostatic pressure.^{6,7} In the absence of external stresses, magnetocrystalline anisotropy should be easily deduced from appropriately oriented single crystal samples. In epitaxial films, the substrate imposes a strain on the film which affects not only Curie temperature and magnetoresistance properties but also the magnetic anisotropy. Jin *et al.* and Kwon *et al.* have demonstrated the effects of strain on the magnetoresistive properties of epitaxial manganite films.^{8,9} Lecoer *et al.* have studied the magnetic anisotropy of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (LSMO) thin films by using Kerr microscopy.¹⁰

In this article, we present magnetic anisotropy results on both films and single crystals of LSMO as measured by torque magnetometry. Detailed studies of the magnetic anisotropy of (001) and (110) LSMO films on (001) and (110) SrTiO_3 (STO) substrates indicate the dominant effect of strain due to the lattice mismatch between the film and substrate.¹¹ Single crystal samples shed light on the magnetocrystalline anisotropy in this material that is masked by the strain anisotropy in epitaxial films.

We studied several different types of LSMO samples: epitaxial films of (001) and (110) orientation and single crystal disks with a (100) axis of rotation. The films of LSMO were grown on (001) and (110) STO ($a=b=c=3.911 \text{ Å}$) substrates using pulsed laser deposition. In this article, we will describe the orientation of the manganite films in terms of the pseudocubic lattices parameters $a'_{\text{bulk}}=b'_{\text{bulk}}=c'_{\text{bulk}}=3.87 \text{ Å}$. The single crystals have a cubic perovskite structure with a rhombohedral distortion and a rhombohedral lat-

tice constant of 7.78 Å . The single crystal orientation will be described in terms of the rhombohedral lattice parameters. Deposition conditions, structural characterization, and the magnetoresistive properties have been described in another publication.^{11,12} Films with thicknesses varying from 500 to 3000 Å were fabricated. The single crystals were grown by the float zone method.¹³ The resulting single crystal rod has the [100] direction at 17° away from its rotational axis as measured by Laue diffraction. A disk sample (2.83 mm radius and 0.57 mm thick) with a (100) axis of rotation was then cut from the rod. Structural characterization indicates excellent crystallinity for the films and crystals and smooth surface morphology for the films.¹¹⁻¹³

Measurements of the magnetic anisotropy of the films and crystals were performed using vibrating sample and torque magnetometry with the magnetic field in the plane of the film and single crystal disk. A Lakeshore vibrating sample magnetometer 7307 was used to make the magnetization measurements and a custom-built torque magnetometer was used to measure the torque as a function of angle on both the epitaxial films and single crystals.

We present here results on the magnetic anisotropy of epitaxial films and single crystals of LSMO. While the magnetic anisotropy of epitaxial films is dominated by strain effects due to the lattice mismatch between the film and the substrate, the single crystals exhibit an anisotropy indicative of the crystal lattice. We measured the magnetic anisotropy of the films on both the torque magnetometer and vibrating sample magnetometer (VSM). In order to measure the anisotropy on the VSM, we first saturate the film to ensure that the sample is initially in a single domain state. Then the magnetization is measured as the field is lowered. We measured the magnetization at various angles that the applied field makes with respect to the crystal axes in the plane of the film. Figure 1 shows a typical plot of a (001) LSMO film. At $H=1 \text{ kOe}$, there is no evidence of angular dependence of the magnetization, thus indicating that the sample is in the saturated state (Fig. 1). Below 900 Oe, which we call the anisotropy field, the sample is no longer saturated in the direction

^{a)}Electronic mail: suzuki@msc.cornell.edu

FIG. 1. Magnetization vs angle ϕ of a (001) LSMO film on (001) STO at room temperature. The field is applied in the plane of the film as a function of angle ϕ as shown in the inset. The sample was initially poled positive and then the magnetization measurements were made at 1 kOe and zero field.

of the applied field as observed in the angular dependence of the magnetization. The angular dependence indicates that [100] and [110] directions are easy and hard, respectively. The fourfold symmetry of Fig. 1 can be explained by either cubic magnetocrystalline or stress anisotropy but not rhombohedral magnetocrystalline anisotropy. In order to distinguish between the two factors, we studied the magnetic anisotropy of (110) oriented films. In these films, the [001], [110], and [111] directions are all in the plane of the film. We observe uniaxial anisotropy in the plane of these films with the easy direction along the [001] direction and the hard direction along the [110] direction. The anisotropy field of $H_K = 840$ Oe determined from magnetization measurements of (110) films is consistent with that of the (001) films.

Torque magnetometer measurements of (110) LSMO films also reveal a uniaxial anisotropy in the (110) plane (Fig. 2). There are three possible explanations for this behavior: cubic or rhombohedral magnetocrystalline or stress anisotropy. If cubic magnetocrystalline anisotropy were to explain the result, the torque L can be expressed as a function of angle θ between the applied field and the [001] direction in the following way: $L = (K_1/4 + K_2/64)\sin 2\theta + (3K_1/8 + K_2/16)\sin 4\theta - (3K_2/64)\sin 6\theta$ where K_1 and K_2 are the first and second order magnetocrystalline anisotropy constants.¹⁴ When we fit the torque curve with the above expression, we obtain K_1 and K_2 from fitting the fourfold and sixfold terms. Now cubic magnetocrystalline would predict a twofold term of $K_1/4 + K_2/64 \sim 7.5 \times 10^3$ ergs/cm³. In fact, we observe a twofold or uniaxial anisotropy contribution of -8.4×10^4 ergs/cm³. This large twofold contribution

FIG. 2. Torque curve of a (110) LSMO film on (110) STO at room temperature in a 2.8 kOe field. The field is applied in the plane of the film as a function of angle θ between the applied field and the [001] direction.

cannot be explained by cubic magnetocrystalline anisotropy or sample misalignment and indicates that there is an additional anisotropy contribution with a hard [110] direction. Furthermore rhombohedral magnetocrystalline anisotropy would predict a uniaxial anisotropy in both the (110) and (100) planes and none in the (001) plane. These predictions are inconsistent with our film results.

Although the symmetry of the magnetic anisotropy of the films are the same when measured by VSM or torque magnetometry, the anisotropy constants derived from the VSM measurements are much larger than those measured by the torque magnetometer. If the anisotropy constant is not constant throughout the sample, it is not surprising that anisotropy constants deduced from anisotropy fields (measured on the VSM) tend to overestimate the average anisotropy constant measured in the torque curves. In fact, Kwon *et al.*⁹ also have observed wide in-plane ferromagnetic resonance lines indicative of a distribution of anisotropies in our films. $H_{ex} = Ms/(dM/dH)|_{H=0}$ is a more appropriate value for the anisotropy field than H_{sat} (the field when M reaches M_s) to estimate an anisotropy constant consistent with torque measurements.¹¹ For example, for the 2500 Å LSMO film, $H_{ex} = 410$ Oe obtained from the magnetization data is consistent with the anisotropy constant $K = 8.4 \times 10^4$ ergs/cm³ deduced from the torque magnetometer data.

Therefore magnetic anisotropy data from epitaxial films on STO indicate that lattice mismatch between the film and substrate induces a strain anisotropy of the order of $K = 8.4 \times 10^4$ ergs/cm³. Further studies of the magnetic anisotropy as a function of film thickness have confirmed the effect of strain especially on thinner films.¹¹ However in single crystals the magnetic anisotropy should be indicative of magnetocrystalline anisotropy. Magnetocrystalline anisotropy includes the effects of lattice distortions that have been the focus of recent scrutiny. To our knowledge, there has been very little work in understanding the magnetocrystalline anisotropy of the doped manganite material. Perekalina *et al.*¹⁵ have observed a uniaxial magnetocrystalline anisotropy of single crystal (La, Sr, Pb)MnO₃ in the (100) and (110) planes and no anisotropy in the (001) planes. They describe the symmetries of their magnetic anisotropy in terms of a rhombohedral magnetocrystalline anisotropy with $K_1 \sim 2 \times 10^4$ ergs/cm³ and $K_2 = 0$.

We have measured the magnetic anisotropy of (100) LSMO single crystal disks grown by the float-zone method in contrast to the Pb flux method used by Perekalina *et al.* We observe a predominantly uniaxial anisotropy with easy and hard directions along the [001]/[010]. Measurement of the magnetic anisotropy from the angular dependence of the magnetization is precluded in such bulk samples where there are significant effects from shape anisotropy. The finite thickness of the disk (0.57 mm in contrast to the 2000 Å of the film) adds a shape anisotropy contribution to such measurements. By contrast, torque measurements of a saturated sample preclude these shape effects. Figure 3 shows the torque curves for a single crystal sample in fields from 0.4 to 1.8 kOe. As soon as we reach a field of 600 Oe, we obtain a saturated torque curve. The torque curve is predominantly twofold with an anisotropy constant of 1.8×10^4 ergs/cm³

FIG. 3. Torque curves of a (100) LSMO single crystal disk, at room temperature and at a variety of fields in the plane of the disk, shows that 600 Oe is required to saturate the sample.

and a fourfold component that is 4% of the twofold contribution. Torque curves measured with clockwise and counterclockwise field rotation are identical, thus showing no evidence of rotational hysteresis (Fig. 4).

In our crystal samples, we obtain an anisotropy constant of $K = 1.8 \times 10^4$ ergs/cm³ in the (100) plane. The discrepancy in anisotropy values compared to those of Perekalina ($K_1 = 2 \times 10^4$ ergs/cm³) may be attributed to the presence of Pb in their samples which may result in structural distortions that affect the magnetic anisotropy.

For a cubic crystal, one would expect fourfold symmetry in the torque curve of the (100) plane which is not what we observe. For a rhombohedral crystal, one would expect twofold magnetocrystalline anisotropy for an untwinned crystal. X-ray diffraction of our single crystal samples indicate that there is significant twinning in the single crystal. While a rhombohedral crystal with all four different kinds of twin domains should exhibit fourfold symmetry in the (100) plane, twinning of two types of domains may not necessarily change the underlying twofold symmetry of the crystal structure. Therefore the observed twofold anisotropy is not inconsistent with rhombohedral magnetocrystalline anisotropy.

FIG. 4. Torque curves of a (100) LSMO single crystal disk measured with the field rotated clockwise and counterclockwise indicate no effects due to rotational hysteresis.

We consider some possible origins of the observed twofold symmetry. Site ordering has been observed in the garnet and TbFe systems to give rise to an anisotropy.¹⁶⁻¹⁸ Our uniaxial anisotropy cannot be explained by growth induced anisotropy due to site ordering since growth induced anisotropy would result in a perpendicular anisotropy in our single crystal disk samples. Our uniaxial anisotropy cannot be explained by misalignment of the (100) axis with the axis of rotation due to cleaving uncertainties or misalignment of the sample holder. The misalignment is to within 3°. The total energy density of a disk sample would be $E = K_{mc} \cos^2 \theta + K_{shape} \sin^2 \theta$ where K_{mc} and K_{shape} are the magnetocrystalline and shape anisotropy, respectively. If the twofold contribution is due to the misalignment, then the second term in the above expression should be equal to 1.8×10^4 ergs/cm³. Given the dimensions of our disk sample, the calculated shape anisotropy is 4.5×10^5 ergs/cm³. Even if our misalignment were 3°, the shape anisotropy term in the above energy density expression would be only 1224 ergs/cm³ and not be able to account for the entire 1.8×10^4 ergs/cm³. We have eliminated some of the possible origins of the strong twofold anisotropy in the (100) plane of the crystal. These observations lead us to conclude that the twofold symmetry that we observe in the (100) plane can be attributed to the rhombohedral magnetocrystalline anisotropy of the LSMO crystal.

We acknowledge Maura Weathers for her help in x-ray diffraction. This project is supported by the NSF through a CAREER award and the Materials Science Center at Cornell University.

We have carried out a study of composite, granular films made by depositing LCMO (a colossal magnetoresistive perovskite) and pure, metallic Au onto MgO and LaAlO_3 substrates. Elevated temperature caused the Au to segregate into small, micron-sized granules. The films were studied by atomic force microscopy, magnetoresistivity, superconducting quantum interference device magnetization measurements, and magnetically modulated microwave absorption. © 1998 American Institute of Physics. [S0021-8979(98)28011-X]

I. INTRODUCTION AND MOTIVATION

A deposition process, recently described by Allen and Cukauskas,¹ was used to grow composite superconducting thin films composed of adjacent YBCO and metallic gold granules. Although scanning electron microscopy micrographs showed a well segregated region of Au and YBCO with large, micron-sized Au grains, transport measurements of these films indicated the existence of Josephson tunneling between YBCO grains, with the separations between grains of the order of only tens of angstroms. The above-mentioned authors concluded that Au diffuses into the grain boundaries, weakening the coupling between YBCO grains, thereby creating granular films with interesting microscopic properties.

Since LCMO ($\text{La}_{1/3}\text{Ca}_{2/3}\text{MnO}_3$) and YBCO are both ceramic perovskites, we expected that a granular Au/LCMO composite can be grown with the same techniques that Allen and Cukauskas used to deposit Au/YBCO films. This expectation proved to be true.

Section II describes the deposition technique and the morphology of the resulting films, while Sec. III summarizes the magnetic and transport measurements. Section IV summarizes the microwave absorption experiments. We are led to conclude that films containing small LCMO granules with diameters of the order of 500 Å can be easily made.

II. FILM PREPARATION AND MORPHOLOGY

First, a Au layer was evaporated onto a cleaned MgO substrate at ambient temperatures and then heated to 800 °C in order to coalesce the Au film into discrete islands on the substrate surface. Next, the sample was silver pasted onto a substrate holder and heated for the LCMO deposition. The LCMO was deposited over the sample using off-axis sputtering as previously described by Broussard *et al.*² The sputtered LCMO filled in the regions between the Au islands but did not stick to the gold, yielding a composite film consisting of micron-sized "islands" of Au protruding from an

"ocean" of LCMO. The relative thickness of the deposited layers determines the filling factor, i.e., the ratio of perovskite to gold.

The morphology of the composite Au/LCMO films was studied using atomic force microscopy (AFM) and scanning electron microscopy (SEM). Figure 1 presents a comparison between the AFM images for a sample with 200 Å of Au and one with 600 Å of Au. For both samples the amount of LCMO deposited is the same (1000 Å). For the 200 Å sample [Fig. 1(a)], we see that the Au has coalesced into islands of $\approx 1.5 \mu\text{m}$ in diameter and $0.5 \mu\text{m}$ in height, which occupy $\approx 28\%$ of the film surface, with the LCMO film occupying the area in between the Au islands. For the 600 Å sample [Fig. 1(b)], we see that the Au islands have begun to coalesce, forming structures up to $7 \mu\text{m}$ in length, which occupy now only $\approx 24\%$ of the film surface. What most distinguishes the two samples is the appearance of smaller islands only $\approx 400 \text{ Å}$ in height above the LCMO film and $\approx 0.5 \mu\text{m}$ in diameter in Fig. 1(b). These smaller islands occupy 16% of the film surface. SEM microscopy was unable to resolve the smaller islands, however energy dispersive analysis by x ray (EDAX) does indicate the presence of Au in the regions between the large Au islands. So it is conceivable that these small islands are due to Au droplets that did not coalesce into the large islands during the annealing stage.

III. MAGNETISM AND TRANSPORT

In Fig. 2(a) we display a plot of the percent of magnetoresistance versus temperature for sputtered LCMO films with three different thicknesses of Au: 200, 400, and 600 Å. Each film contains 1000 Å LCMO. In this case, the percent of magnetoresistance is defined as $[R(1) - R(0)]/R(0)$, where $R(0)$ is the resistance at zero applied field and $R(1)$ is the resistance at 1 T. LCMO is a magnetic perovskite with a Curie temperature $T_c = 250 \text{ K}$, in the vicinity of which a very large, "colossal" magnetoresistance has been discovered.³ A pure LCMO film has a single negative magnetoresistance peak at $\approx 250 \text{ K}$. As the gold granules occupy an increasing

percentage of the total film surface, the primary 250 K peak decreases in intensity, and a secondary peak appears at 190 K. At even larger gold concentrations, the secondary peak merges with the main peak to form a tail.

In Fig. 2(b) we display a plot of percent of magnetoresistance versus temperature for two Au/LCMO granular films which have been manufactured by laser ablation. The ablated sample containing 200 Å Au/1000 Å LCMO displays what appears to be two negative peaks at ≈ 220 and ≈ 180 K. A broad transition at ≈ 165 K appears in the 200 Å Au/200 Å LCMO ablated film, no doubt of inhomogeneous origin. In both Figs. 2(a) and 2(b), the percent of magnetoresistance does not exceed 40%; increasing the gold concentration tends to decrease the magnetoresistance from its bulk value.

It is not unexpected that some broadening of the transition temperature occurs when the LCMO samples become increasingly granular. There are several physical models, some granular and others continuum, which can explain this phenomenon. Because the magnetoresistance can display two negative peaks [e.g., Fig. 2(a)], we are tempted to employ a mean field theory first utilized by Gittleman *et al.*⁴ and others,⁵ which attributes the high temperature peak at T_{c0} to the magnetic ordering of the individual granules, and the low temperature peak at T_c to the ordering of the granules with respect to each other. Such an explanation for the temperature dependence of the magnetic transition in granular Au/LCMO parallels the explanation of the superconducting transition in granular Au/YBCO.¹ (In these granular su-

FIG. 2. (a) Percent of magnetoresistance $\{[R(T) - R(0T)]/R(0T)\} \times 100\}$ vs temperature for granular films composed of 200 Å Au/1000 Å LCMO (diamonds), 400 Å Au/1000 Å LCMO (squares), 600 Å Au/1000 Å LCMO (circles). The LCMO layer was deposited by sputtering. (b) Percent of magnetoresistance $\{[R(T) - R(0T)]/R(0T)\} \times 100\}$ vs temperature for granular films composed of 200 Å Au/200 Å LCMO (circles), and 200 Å Au/1000 Å LCMO (squares). The LCMO layer was deposited by laser ablation.

perconductors, the resistivity starts to drop at the transition temperature T_{c0} of the individual superconducting grains. Finally, at a lower temperature, T_c , the Josephson coupling energy between adjacent grains, causes their phases to lock together, and the sample becomes completely superconducting.)

However, a more likely scenario to that presented above is to attribute T_{c0} to the transition temperature of the very large, "infinite" clusters, and to attribute the low temperature transition (or the "tail" of the primary transition) to smaller grains of LCMO whose transition temperature is depressed by surface interactions. This picture neglects the interaction between the grains.

Turning from resistivity measurements to magnetization measurements, we have measured the zero-field-cooled (ZFC) and field-cooled (FC) magnetization in sputtered Au/LCMO with volumetric ratios of 0.2, 0.4, and 0.6. The results are shown in Fig. 3. The arrows indicate the temperatures of the susceptibility peak of the ZFC susceptibilities. A small measuring field is used (30 G) to minimize the hysteresis of the granules themselves. The superparamagnetic blocking temperature T_B has been variously identified as the temperature at the peak of the ZFC magnetization or the temperature at which the ZFC and FC magnetizations meet.

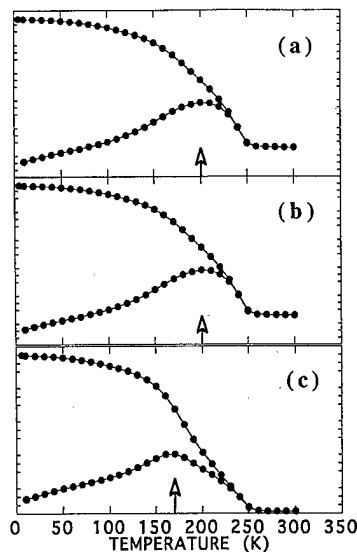

FIG. 3. ZFC and FC magnetization vs temperature for (a) 200 Å Au/1000 Å LCMO, (b) 400 Å Au/1000 Å LCMO, and (c) 600 Å Au/1000 Å LCMO (circles). The LCMO layer was deposited by sputtering. The arrows indicate the blocking temperature in the ZFC data.

Assuming that the magnetic anisotropy energy exceeds the interparticle interaction, the volume of an average grain in a static magnetization experiment can be estimated by the relation⁶

$$(1/2)KV \approx 25k_B T_B. \quad (1)$$

Here, V is the volume of the grain, and K is the dominant anisotropy energy. Utilizing ferromagnetic resonance techniques, Ramachandran *et al.*⁷ found the demagnetizing field, $H_D = 4\pi M \approx 5000$ G, and a negligible crystalline anisotropy field, $H_A \approx 0$, for LCMO. Using the dipolar shape anisotropy $2\pi M_s^2$ as the dominant dipolar anisotropy energy in Eq. (1), and also using $T_B = 200$ K as appropriate for the 600 Å Au/1000 Å LCMO sample shown in Fig. 3(c), we obtain a value of 400 Å as an estimate for the grain diameter based on the magnetization studies. This is the correct magnitude for the fine structure visible in the micrographs of Fig. 1(b), and absent in Fig. 1(a) with less Au, from which we conclude that the metallic Au may serve to separate LCMO grains by diffusing into the grain boundaries. Similar tentative conclusions have been reached by Allen and Cukauskas in their studies of superconducting Au/YBCO composites.¹

Each of the three Au/LCMO magnetization curves shown in Fig. 3 represents a different concentration of Au. It can be seen that the temperature of the susceptibility peak moves to lower temperatures as the Au content increases. We can attempt to explain this fact using Eq. (1), and assuming that increasing Au content causes the average volume V of the grains to decrease, thereby decreasing T_B .

IV. MICROWAVE ABSORPTION

Magnetically modulated microwave absorption (MAMMA) is a microwave absorption technique which uti-

FIG. 4. MAMMA spectra as a function of temperature of (a) a pure LCMO film and (b) a 600 Å Au/1000 Å LCMO granular film. The LCMO layer was deposited by sputtering.

lizes magnetic field modulation and a temperature sweep.⁸ The absorption is monitored using the conventional electron spin resonance (ESR) spectroscopic methodology, which involves field modulation and phase sensitive detection at the modulation frequency. The difference is that one scans along the temperature axis at a fixed magnetic field value rather than scans along the magnetic field at a fixed temperature.

In Figs. 4(a) and 4(b) we display the MAMMA response (the field-modulated microwave absorption curve as a function of temperature) at an applied field of ≈ 10 kG for a thin film of pure LCMO and a granular film of 600 Å Au/1000 Å LCMO. The response is characterized by a derivativelike peak occurring at a temperature corresponding to the peak in the magnetoresistance.

Figure 4(a) exhibits a single peak at ~ 250 K, the Curie temperature of LCMO, as expected. Figure 4(b) exhibits two peaks: a smaller peak near the Curie temperature of the individual grains (~ 250 K) and a larger peak near a temperature we have identified as either the ordering temperature of the grains with respect to one another or as the ordering temperature of the very small grains. The microwave absorption serves to verify the two-peaked nature of the magnetoresistance.

Magnetic and transport properties of radiation damaged $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3.0}$ thin films

V. M. Browning,^{a)} R. M. Stroud, W. W. Fuller-Mora, J. M. Byers, M. S. Osofsky, D. L. Knies, K. S. Grabowski, D. Koller, J. Kim, D. B. Chrisey, and J. S. Horwitz
Naval Research Laboratory, Washington, District of Columbia 20375

Magnetization and resistivity measurements are reported for a series of radiation damaged $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ pulsed laser deposited thin films. When plotted as a function of activation energy, trends in the electrical transport properties are similar to those exhibited in the magnetic properties. A sharp drop in both T_c and T_p in samples with activation energies greater than ~ 110 meV suggests a "decoupling" of the magnetic and transport properties. The results suggest the magnetic order is no longer sufficient to delocalize the system of the extra disorder induced by the radiation damage.
 [S0021-8979(98)38011-1]

I. INTRODUCTION

The mixed valent metal-oxide perovskite $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3.0}$ (LCMO) is known to exhibit "colossal" magnetoresistance¹ (CMR) near a transition from insulating to metallic behavior. This transition occurs at a temperature, T_p , at which the resistivity reaches its maximum value and which is nearly coincident with the onset of ferromagnetic ordering of the Mn spins at the Curie temperature, T_c . Although the ferromagnetism in these materials is attributed to a double exchange mechanism mediated by the $\text{Mn}^{3+}-\text{O}-\text{Mn}^{4+}$ bond,² the origin of the metal-insulator transition in these materials remains a subject of considerable debate. In particular, the high temperature activated behavior, although generally believed to be some form of hopping mechanism, is not well understood. Since a prerequisite for hopping transport is the formation of spatially localized states, it has been speculated that magnetic disorder above the Curie temperature may be the source of localization in the CMR materials. However, Millis *et al.*,³ have argued that the double exchange mechanism alone is not sufficient to account for a disorder driven metal-insulator transition in this system and conclude that lattice distortions play a necessary and crucial role in the observation of a metal-insulator transition and the resulting CMR effect. Experimental results to date have yet to yield a definitive conclusion regarding the role of structure and magnetism in the CMR materials.

In an effort to better understand the relationship between structure, magnetism, and transport in the CMR materials we have looked at the evolution of both the magnetic and transport properties in radiation damaged pulsed laser deposited LCMO thin films. It has previously been demonstrated that ion beam irradiation can be used to "tune" both the magnetic and transport properties in the CMR materials.⁴ We have used this technique to produce a series of LCMO thin films with varying amounts of radiation damage. Our results reveal that both the Curie temperature and peak temperature exhibit a sharp drop in magnitude in samples with activation energies larger than ~ 110 meV, thereby establishing a rela-

tionship between transport and magnetism in this system. Further study of this relationship may lead to a more clear understanding of how the two phenomena are coupled in the CMR materials.

II. EXPERIMENT

The LCMO films were grown by pulsed laser deposition on single crystal (100) LaAlO_3 substrates. Complete details of the deposition procedure can be found elsewhere.⁵ A post-deposition anneal at 1000°C in an oxygen atmosphere was performed to oxygenate the as-deposited films and to minimize extrinsic structural defects. After annealing, the films were irradiated with 10 MeV I ions in order to introduce a controlled quantity of structural defects. The flux of incident ions ranged from 5.0×10^{12} ions/cm² to 20.0×10^{12} ions/cm² and were estimated by TRIM simulations⁶ to result in displacement damage of between 0.006 and 0.021 displacements per atom (d.p.a.). The incident ion energy was chosen to produce uniform damage and implantation of the incident ions into the substrate, in contrast with an earlier study of Ar irradiation in which TRIM simulations indicated nonuniform damage and implantation of the ions in the films.⁴

The transport properties of the films were characterized by measuring the temperature dependence of the resistivity while cooling the films in a closed cycle refrigerator. The resistivities of the samples were measured using a standard four-probe technique. The measuring currents ranged from 10 nA to 100 μA depending on the magnitude of the resistivity being measured.

The magnetic measurements were taken using a superconducting quantum interference device (SQUID) magnetometer. Hysteresis curves, which allowed measurement of the saturation magnetization and coercivity, were taken by sweeping field at fixed temperature ($T=10$ K), while the temperature dependent magnetization measurements, which allowed measurement of the Curie temperature, T_c , were taken by cooling the sample in an applied field ($H=1000$ Oe). All of the magnetization measurements were corrected for the diamagnetic signal of the substrate as determined from a series of measurements on blank LaAlO_3

^{a)}Electronic mail: browning@anvil.nrl.navy.mil

FIG. 1. Resistivity vs temperature data for radiation damaged pulsed laser deposited LCMO thin films.

substrates. There is an estimated 10% uncertainty in the absolute magnitude of the magnetization values due to the uncertainty in calculating the sample volume.

III. RESULTS AND DISCUSSION

Figure 1 shows the resistivity versus temperature curves for the LCMO films. The effect of the radiation damage manifests itself as an increase in the resistivity as well as a reduction in T_p . For the most heavily irradiated samples, no peak in resistivity was observed down to ~ 40 K where the resistance became too large to measure in our apparatus. These two films were further studied at low temperatures by using an electrometer to confirm that the resistivity of the films at 4.2 K was greater than $10^4 \Omega\text{-cm}$.

The exact mechanism which dominates transport at temperatures above T_p remains unclear. In a simple thermally activated semiconducting system, the resistivity is expected to exhibit a temperature dependence with $\rho = \rho_0 \exp(\Delta/k_B T)$. If the conduction is by small polarons, as suggested by Millis *et al.*,³ then the resistivity should exhibit a temperature dependence $\rho = \rho_0(T) \exp(\Delta/k_B T)$ where $\rho_0(T) \sim T$ for adiabatic polarons and $\rho_0(T) \sim T^{3/2}$ for non-adiabatic polarons. It has also been suggested that the activated behavior may be due to variable range hopping (v.r.h.)⁷ which results in a temperature dependent resistivity $\rho = \rho_0 \exp(T_0/T)^{1/4}$. In general, with limited temperature range, it is difficult to discriminate between these models. In the present study, it was found that all of the models could be equally well fit to the data. The activation energies ($\Delta = k_B T_0$) obtained using a semiconducting fit are 57.0 meV for the undamaged sample and 100.9, 111.5, 117.5, and 117.9 meV for the samples irradiated with 5.0×10^{12} , 10.0×10^{12} , 15.0×10^{12} , and 20.0×10^{12} I ions/cm², respectively. In order to confirm that the error in the extracted activation energy using the data near T_p for the low damage samples was minimal ($< 5\%$), the temperature range of the undam-

FIG. 2. Field dependence of the magnetization ($4\pi M$) of radiation damaged pulsed laser deposited LCMO thin films. The inset shows the low field behavior for the undamaged, 0.006 d.p.a. and 0.021 d.p.a. films.

aged sample was increased by measuring its resistivity up to 400 K (data not shown in Fig. 1) and the fit was reapplied over the entire data range.

Hysteresis loops taken on the various samples are shown in Fig. 2. Of note is the sharp decline in the saturation magnetization and the significant increase in the coercive field with increasing damage (see Fig. 2 inset). It is also interesting to note that the most heavily damaged samples continue to exhibit a residual paramagnetism above the saturation field. This observation is consistent with what one expects to see in a ferromagnetic system that is becoming increasingly disordered and/or frustrated. Further evidence for this can be seen in the temperature dependence of the magnetization as plotted in Fig. 3. These data show a reduction in T_c with

FIG. 3. Temperature dependence of the normalized magnetization of a series of pulsed laser deposited LCMO films with damage levels ranging from: 0.000 d.p.a. (○), 0.006 d.p.a. (□), 0.011 d.p.a. (◇), 0.016 d.p.a. (×), and 0.021 (+). The inset shows the data plotted as a function of reduced temperature, $(T_c - T)/T_c$.

FIG. 4. Curie temperature, T_c , plotted against activation energy, Δ , for several series of radiation damaged LCMO thin films. The circles represent data for the series of samples which are the focus of the current study. Additional data points come from oxygen deficient LCMO films irradiated with Si ions (triangles) and LCMO films irradiated with I ions grown from a Mn-rich target (squares). The inset shows the corresponding data for the T_p values as a function of Δ .

increased damage and when plotted versus reduced temperature, $(T_c - T)/T_c$, significant broadening of the transition region is evident (see Fig. 3 inset). These results are interpreted as indicative of a weakening and broadening of the magnetic exchange distribution both of which are attributed to the increased disorder resulting from the radiation damage.

The reduced $4\pi M$ and T_c values, the increased coercivity, and the observation of paramagnetism at high fields below T_c , are all features consistent with the behavior seen in both superparamagnetic and spin-glass systems. Although it is impossible based upon the current experimental results to distinguish between the two effects, considering the length scale (~ 20 – 50 Å) and homogeneity associated with the atomic displacements, we consider it more likely that the results are a result of spin-glass formation. Further study of the temperature dependent magnetization as a function of field-cooled and zero-field cooled initial conditions as well as measurements at higher fields will help to clarify this issue. However, it has recently been reported by Cai *et al.*⁸ that spin-glass behavior can be induced via spin disorder in Fe-doped LCMO. Therefore it is likely that the spin disorder introduced by the radiation damage in the current study, and by Fe substitution in Cai *et al.*'s samples, result in similar effects.

Figure 4 plots the T_c values versus activation energy obtained from the samples reported on in this study together with values obtained from two other series of radiation damaged pulsed laser deposited LCMO films. The additional data sets come from one series of oxygen deficient LCMO films that were irradiated with Si ions and a series of I irradiated

LCMO films that were prepared from a Mn-rich target. The inset to Fig. 4 shows the dependence of T_p as a function of activation energy. Both curves exhibit a sharp drop near 110 meV, beyond which the metal-insulator transition is completely suppressed despite the existence of a ferromagnetic transition. This result does not change qualitatively when using values for activation energies obtained using the other model dependent expressions for resistivity discussed earlier and suggests that the increasing disorder results in a decoupling of the magnetic and electronic transport properties. This implies that in samples which exhibit activated behavior with $\Delta > 110$ meV (as determined using a semiconducting expression for the resistivity), the magnetic ordering is no longer sufficient to delocalize the system. The fact that this trend is seen in samples obtained from several series prepared under different processing conditions suggests that this behavior may be universal in the LCMO system.

IV. CONCLUSION

In summary, resistivity and magnetization data presented for radiation-damaged LCMO thin films show similar trends when examined as a function of radiation damage. These results show, in agreement with previous reports, that the ion irradiation has a deleterious effect on both the magnetic and transport properties and that the radiation damage results in spin disorder which likely is responsible for the observation of behavior similar to that observed in spin-glass systems. An examination of the trends in the magnetic and transport properties as a function of radiation damage has established a relationship between the onset of magnetic ordering (Curie temperature) and the activation energy as determined from the high temperature resistivity measurements.

We report on a systematic investigation of strain-induced lattice distortion effects on the crystal structure and transport properties of as-grown and postannealed ultrathin $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ epitaxial films grown on LaAlO_3 (001) substrates by pulsed laser deposition. The resistivity of the as-grown films is critically dependent on the thickness, i.e., 100 Å thick films show insulating behavior, 300 Å thick films show metal-insulator transitions, and 500 Å thick films show metallic behavior. However, all the annealed films show identical metallic behavior. Conventional θ - 2θ x-ray scans with momentum transfer (q) along the [001] direction, and θ - 2θ scans of the (103) and (113) peaks, with q having a component perpendicular to the growth direction, were used to measure the out-of-plane and in-plane lattice parameters of the sample. Φ scans of the (103) and (113) peaks revealed a fourfold symmetry which is consistent with a tetragonal unit cell. These data conclusively show that significantly elongated tetragonal structures ($c/a = 1.02$ – 1.04) are insulating whilst films with cubic unit cells, relaxed either due to annealing or as a function of thickness, have metallic characteristics. © 1998 American Institute of Physics. [S0021-8979(98)52911-8]

The transport properties of manganite perovskites $\text{R}_{1-x}\text{A}_x\text{MnO}_3$ ($\text{R}=\text{La, Pr, Nd}$, $\text{A}=\text{Ca, Sr, Ba}$) in the double exchange formalism¹ is sensitive to both the Mn–O bond distance ($d_{\text{Mn-O}}$) and the Mn–O–Mn bond angle (θ). Slight changes in $d_{\text{Mn-O}}$ or θ affect the on-site coulomb correlation energy and/or bandwidth and may lead to a metal–insulator transition. Note $d_{\text{Mn-O}}$ and θ can be altered either by substitutions,^{2,3} external pressure,⁴ or, in a controlled fashion, by strain due to epitaxial growth on lattice-mismatched substrates.^{5–7} In the latter case, the strain is also a function of the thickness, annealing conditions, and mechanisms of strain relaxation. Although there exist numerous studies of the effect of lattice changes, induced by chemical substitutions and external pressure, on the transport and structure of manganite perovskites, there has been little investigation on the effect of lattice distortion induced by substrate strain on the transport and structure. In addition, the reports were focused on relatively thick films (thickness ≥ 1000 Å) most of which were post annealed at high temperature (for example, 900 °C) at which significant lattice relaxation can occur making the films unsuitable for strain study. Hence, we have chosen to study lattice distortion, strain, and its influence on the transport properties in the $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ (LSMO) system, which is a metallic and ferromagnetic compound with a high transition temperature of 370 K.² Epitaxially grown LSMO[001] \parallel LaAlO_3 [001] films are expected to be under compressive strain since $d_{\text{LSMO}}(3.88 \text{ Å}) > d_{\text{LAO}}(3.78 \text{ Å})$. In this article, we report on the critical thickness and annealing (strain relaxation) dependence of the transport and structural properties of such ultrathin [001]LSMO/[001]LAO films.

LSMO films with thickness ranging from 100 to

500 Å, were deposited from a target of composition $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ by pulsed laser deposition on LaAlO_3 (001) substrates at 640 °C/300 mTorr O_2 ; a condition that gives optimal quality of 100 Å thick films (low resistivity, high transition temperature, large residual ratio). After the deposition the films were cooled down to room temperature at 10 °C/min in an oxygen pressure of 400 Torr. Each wafer was cut into two pieces—one half was left as grown and the other half was annealed at 900 °C 1 bar O_2 /10 h. The temperature dependence of the dc resistivity in a field, H ($=1 \text{ T}$) and zero field, was measured using a standard four-probe technique. The field was applied in a direction perpendicular to the film surface and the current direction.

X-ray diffraction data were obtained using an 18 kW rotating Cu anode generator equipped with a four-circle sample goniometer. The samples were scanned with the momentum transfer vector \mathbf{q} having components both parallel and perpendicular to the growth direction of the samples. The interplanar distance along the [001] direction, assuming a perovskite unit cell, was determined from θ - 2θ scans with \mathbf{q} along the growth direction. The in-plane lattice parameters were determined from θ - 2θ scans of the (103) and (113) peaks, with \mathbf{q} having a component perpendicular to the growth direction of the sample. For all samples, Φ scans of the (103) and (113) peaks revealed a fourfold symmetry consistent with a tetragonal unit cell (i.e., $a=b \neq c$, where c is (001) lattice parameter). The [100] direction of the sample and the LaAlO_3 substrate (assuming a pseudoperovskite unit cell) coincided with one another.

Figure 1 shows representative x-ray data from both annealed and as-grown 100 Å thick samples. Similar results were obtained from the 300 and 500 Å samples, although the peaks in the thicker samples were generally narrower and more intense. The data in Fig. 1(a) were obtained with \mathbf{q}

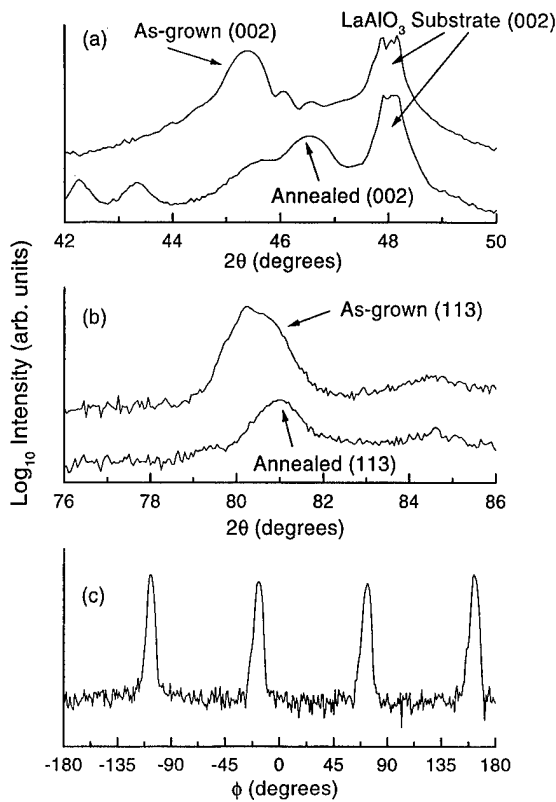

FIG. 1. θ - 2θ scans with q along the [001] growth direction (a) and the [113] direction (b) for both annealed and as-grown 100 Å thick samples (top and bottom scans, respectively). The scans from the annealed and as-grown samples were displaced from one another in graphs (a) and (b) for greater clarity. The peaks due to the LaAlO_3 substrate, indexed using a pseudoperovskite unit cell, are also indicated. Note (c) is a Φ scan of the (103) reflection of the annealed sample, which shows a fourfold symmetry characteristic of the pseudoperovskite structure. All samples in this study had the same fourfold symmetry, with the [100] direction coinciding with that of the LaAlO_3 substrate.

along the [001] direction, so that the sample peaks correspond to the (002) reflection. In both of these scans, the peak near $2\theta=48^\circ$ is a substrate peak. The top scan, measured in the as-grown sample, shows a single peak at approximately $2\theta=45.5^\circ$, while the other, smaller peaks result from the finite thickness of the film. The bottom scan in Fig. 1(a), obtained from the annealed sample, shows several peaks, the strongest of which appears near $2\theta=46.5^\circ$. The other

TABLE I. Lattice parameters of $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3/\text{LaAlO}_3$ thin film samples determined from x-ray diffraction data. The c axis represents the lattice parameter along the growth [001] direction, while the a axis represents the [010] and [100] directions. The corresponding Mn-O-Mn bond angles (θ) and the Mn-O bond distances, both in-plane and out-of-plane are also shown.

Sample	c (Å)	a (Å)	d_{out} (Å)	θ_{out}	d_{in} (Å)	θ_{in}
100 Å as-grown	3.99	3.82	2.00	180°	1.96	151°
100 Å annealed	3.91	3.87	1.96	171°	1.96	160°
300 Å as-grown	3.98	3.85	1.99	180°	1.96	156°
300 Å annealed	3.90	3.88	1.95	167°	1.96	162°
500 Å as-grown	3.91	3.82	1.96	171°	1.96	151°
500 Å annealed	3.88	3.87	1.96	162°	1.96	160°
bulk	3.88	3.88	1.96	162°	1.96	162°

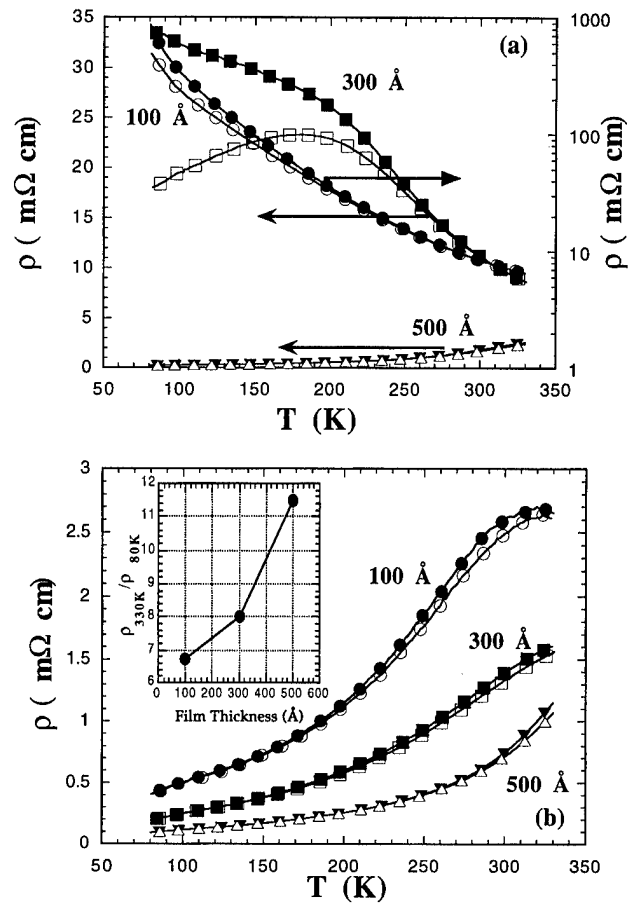

FIG. 2. Temperature dependence of the resistivity of $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ films with thickness from 100, 300, 500 Å thick as-grown (a) and annealed films (b) without field (full symbol) and with an applied field of 1 T (empty symbol). Inset shows the resistivity ratio $\rho_{330\text{K}}/\rho_{80\text{K}}$ as a function of thickness.

weaker peaks could be due to different phases formed during the annealing process. Clearly, the effect of annealing is to shift the peaks to higher angles, which means that the (001) interplanar distance contracts. The scans in Fig. 1(b) were obtained with q along the [113] direction. The top scan again represents the as-grown sample, while the bottom scan represents the annealed sample. The effect of annealing in this case is to shift the peak to higher angles. Figure 1(c) is a Φ scan of the (103) reflection of the annealed 100 Å sample, showing the fourfold symmetry characteristic of the tetragonal crystal structure. All samples showed the same fourfold symmetry. From scans such as those shown in Figs. 1(a) and 1(b), the in-plane and out-of-plane lattice parameters were calculated assuming that the [100] and [010] in-plane directions are equivalent, and that the unit cell is tetragonal. Similar scans of the (103) reflection were used to confirm the results. The results are shown in Table I. It is clear that annealing causes the c axis (along the growth direction) to contract while the a axis (in the plane) expands.

The temperature dependence of the resistivity for the as-grown and annealed films is shown in Fig. 2. The resistivity of the as-grown films [Fig. 2(a)] shows a critical dependence on thickness (t). For $t=100$ Å, it is completely insulating over the entire temperature range investigated with a significant magnetoresistance (MR) effect observed below

200 K. MR increases with a decrease in temperature and reaches $\sim 50\%$ at 1 T and 80 K. However, the absolute magnitude of the resistivity at 80 K is $\sim 1000 \text{ m}\Omega \text{ cm}$ (or $\sim 1 \Omega \text{ cm}$) and rather small compared to that of insulating bulk samples ($> 10^3 \Omega \text{ cm}$).² For $t=300 \text{ \AA}$, the zero-field resistivity is also insulating (with the magnitude of the resistivity smaller than that for $t=100 \text{ \AA}$), but when a field of 1 T is applied the resistivity, $\rho_{H=1\text{T}}(T)$ is suppressed below 270 K and shows a peak around 180 K, with metal-like behavior at lower temperatures. The MR for $t=300 \text{ \AA}$ was found to increase with decreasing temperature. Unlike the above two cases, for $t=500 \text{ \AA}$ a metallic behavior with a room temperature resistivity of $\sim 2 \text{ m}\Omega \text{ cm}$, along with a large MR effect near and above room temperature, but with insignificant MR at low temperature, is observed.

Contrary to the critical thickness dependence of resistivity and MR for the as-grown films, the annealed films [Fig. 2(b)] uniformly show a metallic behavior with significant MR above room temperature. However, the magnitude of the resistivity decreases with an increase in film thickness. For example, the resistivity at 330 K, $\rho_{330\text{K}}$ is $2.7 \text{ m}\Omega \text{ cm}$ for 100 \AA , $1.6 \text{ m}\Omega \text{ cm}$ for 300 \AA , $1.2 \text{ m}\Omega \text{ cm}$ for 500 \AA . The resistivity ratio $\rho_{330\text{K}}/\rho_{80\text{K}}$ increases with increasing film thickness— $\rho_{330\text{K}}/\rho_{80\text{K}} \sim 6, \sim 8, \sim 12$ for 100 \AA , 300 \AA , and 500 \AA thick films, respectively. Moreover, the thicker the film the higher the resistivity peak temperature. The temperature dependence of resistivity reveals that the 100 \AA thick film exhibits a resistivity peak at 320 K, 300 \AA thick film exhibits a resistivity approaching a peak, and the 500 \AA thick film exhibits resistivity with a sharp increase.

Changes in lattice constants of perovskites determine two key structural parameters that impact on their transport properties: Mn–O–Mn bond angle (θ) and bond distance ($d_{\text{Mn-O}}$). (Note: both in-plane and out-of-plane values are shown in Table I). However, it has been shown that for $\text{R}_{0.67}\text{A}_{0.33}\text{MnO}_3$ ($\text{R}=\text{La, Pr, Nd, Y}$; $\text{A}=\text{Ca, Sr, Ba}$), changes in (R , A) site ionic size only affect θ , with $d_{\text{Mn-O}}$ remaining unchanged ($d_{\text{Mn-O}}=1.96 \text{ \AA}$).⁸ This corresponds to a maximum lattice parameter of 3.92 \AA . Hence, it is reasonable to assume that larger values of the lattice parameter imply stretching of $d_{\text{Mn-O}}$ (θ fixed at 180°) and smaller lattice parameters imply a contraction of θ ($d_{\text{Mn-O}}$ fixed at 1.96 \AA). In the as-grown films, a is $\sim 3.82\text{--}3.85 \text{ \AA}$ but c depends on film thickness, i.e., $c=3.99 \text{ \AA}$ for $t=100 \text{ \AA}$ and $c=3.91 \text{ \AA}$ for $t=500 \text{ \AA}$. Thus, the thickness dependence of the resistivity as a function of temperature of as-grown LSMO thin films may be related to changes in the c parameter. For bulk $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$, where $d_{\text{Mn-O}}=1.96 \text{ \AA}$ and $a=c=3.88 \text{ \AA}$,² θ is found to be $\sim 162^\circ$. For tetragonally distorted LSMO thin films θ and $d_{\text{Mn-O}}$ are, in principle, different along the a (in-plane) and c (out-of-plane) axis directions. For the as-grown films, the in-plane Mn–O–Mn bond angle, θ_{in} is $\sim 151^\circ\text{--}156^\circ$ and this decrease in the bond angle (with respect to the bulk) may significantly reduce the double exchange interaction. However, θ_{in} and d_{in} are independent of thickness and may not explain the thickness dependence of the resistivity. On the other hand, the out-of-plane Mn–O–Mn angle, θ_{out} for the as-grown films is $\sim 180^\circ$ and the

out-of-plane Mn–O distance, d_{out} is significantly stretched (Table I). Note d_{out} for the insulating, $t=100 \text{ \AA}$, as-grown film is greater than that for metallic $t=500 \text{ \AA}$ film by 0.04 \AA . The influence of the bond distance $d_{\text{Ti-O}}$ (distance between Ti and O) on the transport properties has been reported⁹ for the bulk, cubic perovskite ($\theta=180^\circ$ between Ti–O–Ti) compound $\text{Nd}_{1-x}\text{Ba}_x\text{TiO}_3$ (NBTO) where a small increase in $d_{\text{Ti-O}}$ ($\sim 0.02 \text{ \AA}$) is responsible for a change from metallic to insulating behavior for $0.7 \leq x \leq 0.9$. The change in $d_{\text{Mn-O}}$ in LSMO thin films, particularly in the out-of-plane direction, is greater than the change in $d_{\text{Ti-O}}$ of NBTO and may be responsible for its insulating behavior. However, there are important differences in the electronic transport between LSMO and NBTO. Whilst the conduction pathway in bulk NBTO is three dimensional, in LSMO thin films the conduction pathway is quasi-two dimensional. Thus, the difference in c for the as-grown films may be responsible for the critical dependence of the resistivity on the film thickness for as-grown films. The quasi-two-dimensional conduction path in ultrathin films of LSMO may be responsible for the observed correlation between the c -axis lattice parameter and the resistivity, pending future investigation.

Preliminary transmission electron microscope measurements¹⁰ show that the 100 \AA thick film relaxes upon annealing by forming a dislocation network with a periodicity determined by the lattice mismatch between the substrate ($d=3.78 \text{ \AA}$) and the film ($d=3.88 \text{ \AA}$). For all films, after annealing, the c axis contracts and the a axis expands resulting in a cubic structure with $a=c \sim 3.88 \text{ \AA}$. There is neither change in a , c , nor the temperature dependence of the resistivity as a function of thickness. The minor differences, i.e., the magnitude of the resistivity and ratio $\rho_{300\text{K}}/\rho_{80\text{K}}$, may be due to variations in the dislocation network created to accommodate the strain. Detailed electron microscopy work to further understand the role of the microstructure, interdiffusion at interface, and strain relaxation mechanism are in progress.

Powder and sintered samples of $\text{La}_{0.9}\text{MnO}_3$ (LMO) and $\text{La}_{0.62}\text{Y}_{0.07}\text{Ca}_{0.31}\text{MnO}_3$ (LYCMO) are used in this study. The two initial calcined in air powders have almost identical ferromagnetic properties with $T_c \approx 250$ K, and saturation magnetization of $\sigma \approx 90$ emu/gm corresponding to $\text{Mn}^{4+}(0.3)/\text{Mn}^{3+}(0.7)$. Heating the calcined powders in argon to high temperatures lowers T_c to ≈ 120 K; however, subsequent oxygen annealing brings back the high T_c form. The LYCMO remains ferromagnetic with $\sigma \approx 90$ emu/gm in both heat treatments but only has a colossal magnetoresistance (MR) for $T_c \approx 120$ K. In contrast the LMO with $T_c \approx 120$ K has σ reduced to one-half its ferromagnetic value and the MR is almost zero. Neutron diffraction shows only the ferromagnetic structure below T_c for LYCMO but the low magnetization of LMO is best interpreted as a mixed ferro-antiferromagnetic structure rather than a canted one. © 1998 American Institute of Physics. [S0021-8979(98)20611-6]

Our previous studies of a self-doped $\text{La}_{1-x}\square_x\text{MnO}_{3-\delta}$ perovskite vacancy (\square) structure showed different magnetic and magnetoresistance properties between films and bulk samples.¹ Preparation and annealing procedures also caused significant changes in the bulk properties. In this article we look at the changes induced in bulk $\text{La}_{0.9}\square_{0.1}\text{MnO}_{3-\delta}$ (LMO) systematically and compare it to $\text{La}_{0.62}\text{Y}_{0.07}\text{Ca}_{0.31}\text{MnO}_{3-\delta}$ (LYCMO) which has a "colossal" magnetoresistance (CMR) discovered by Jin *et al.*² and by Chen *et al.*³ The two compositions LMO and LYCMO are chosen because they have the same mixed valency of Mn and comparison should help our understanding about magnetic and transport properties in these oxides.

To facilitate the presentation Table I lists the various samples studied, their preparation, and structure data. The initial powders are obtained by the reaction of high purity ($\text{La}_2\text{O}_3, \text{MnO}, \text{CaCO}_3$) component oxides or carbonates heated in air at 1050°C . These are designated as calcined in Table I. Subsequent oxygen annealing did not change the calcined powder sample magnetic properties. To cause changes it is necessary to heat the sample in argon to reduce the oxygen content of the powder. Sintered bar samples are prepared from the calcined powders at temperatures of $1550\text{--}1600^\circ\text{C}$ for 16 h at which temperatures there is evidently a loss of oxygen. It is necessary to reanneal in oxygen to obtain magnetic properties for the bars similar to the original calcined powders.

Magnetic data for the two calcined powders are plotted in Fig. 1(a) for LMO and in Fig. 2(a) for LYCMO. Since these samples were adjusted to have the same valency distribution of Mn, it is not surprising that they have about the same Curie temperature (T_c) and the same saturation magnetization σ_s . Assuming O_3 per formula unit (i.e., $\delta=0$)

both compositions have the ratio $\text{Mn}^{4+}(0.3)/\text{Mn}^{3+}(0.7)$. Using spin only of Mn^{4+} and Mn^{3+} as $3n_B$ and $4n_B$ Bohr magnetons, respectively, with ferromagnetic alignment we calculate $\sigma_s = 90.7$ emu/gm for LMO and $\sigma_s = 99.6$ emu/gm for LYCMO. The measured values estimated for $1/H \rightarrow 0$ are 90 emu/gm for LMO and 94.5 emu/gm for LYCMO and the measured σ_s are in reasonable agreement with the calculated values. Curie temperatures estimated from low field magnetization are illustrated in Fig. 1(a) for $H = 150$ Oe. The θ intercept is obtained from the linear portion of the reciprocal susceptibility ($1/\chi_M$) projected to the horizontal axis as given by the Curie-Weiss law $\chi_M = C_M/(T - \theta)$. The molar Curie constant C_M is proportional to the square of the average effective moment $(\mu_{\text{eff}})^2 = g^2 S(S+1)$ of the Mn ions with spin S and $n_B = gS$. To obtain μ_{eff} the relation $8C_M = (\mu_{\text{eff}})^2$ can be used. Reciprocal susceptibilities are plotted for each of the samples studied. These plots are useful not only to obtain μ_{eff} but the departure of $1/\chi_M$ from linearity is a measure of the short range order or cluster formation⁴ of the Mn magnetic moments above T_c . From molecular field theory the θ temperature intercept is a measure of the sign and strength of the exchange interactions between neighboring Mn ions. Where short range order is strong, the Curie temperature is depressed and $\theta > T_c$. In the two calcined samples, Figs. 1(a) and 2(a) $\theta \approx T_c$, indicating very little short range order.

In Figs. 1–4 values of C_M are marked for each $1/\chi_M$ linear plot. These values are all larger than expected and give Mn atomic moments of $4\text{--}5 n_B$ as compared to the $3.7 n_B$ expected for $\text{Mn}^{4+}(0.3)/\text{Mn}^{3+}(0.7)$ ratio. The high values of C_M are evidently due to a small amount of short range order which persists up to 400 K. Magnetic data for the calcined powder heated in argon are shown in Figs. 1(b) and 2(b). For LMO there is a decrease in T_c , θ , and σ_s , but for LYCMO, although a large decrease in T_c is obtained, θ and σ_s change very little. In addition, the reciprocal susceptibility for LY-

^aThe bar samples Figs. 3–6 are sintered and subsequently oxygen annealed.

CMO [Fig 2(b)] now shows a significant departure from linearity indicating short range order or clusters of Mn moments, an effect also found in films.⁵ The change in LMO due to argon annealing shows $\theta < T_c$, meaning that negative exchange interactions are now present. Such interactions cause partial antiferromagnetic alignment of the Mn moments. As we can note from Table I, neutron diffraction measurements have peaks indicating that there is a canted or mixed magnetic structure⁶ composed of ferro- and antiferromagnetic regions. The most probable magnetic structure for LMO can be obtained by comparing the transverse (AF) and parallel (F) spin components from neutron diffraction peaks with estimates of AF/F from magnetization data. We find very poor agreement for a canted structure, but for a mixed phase the volume ratio AF/F is in better agreement for the two sets of measurements if we use the high field magnetization data. We also note that there is a change in crystal structure⁷ for LMO going from a rhombohedral cell for the calcined powder to an orthorhombic cell for the argon anneal. This may be also a reason for the decrease in T_c and σ_S and the mixed magnetic structure. As we shall discuss, this sample has lost its electrical conductivity and is now a semiconductor. As seen in Table I, the powder LYCMO remains

FIG. 2. (a) Plots of σ and $1/\chi_M$ for LYCMO powder after the initial calcine. Note the similarity to calcined LMO in Fig. 1(a). (b) Magnetic data for LYCMO powder after annealing in argon.

the same cubic perovskite for both the calcined and the argon anneal. The neutron diffraction measurement did not indicate any magnetic structure above T_c in the region of short range order, nor was it possible to establish that clusters of aligned Mn magnetic moments exist because of statistical uncertainty in the data. Below T_c a ferromagnetic structure is observed.

Our second group of measurements is on sintered samples. Bars are cut approximately $10 \times 3 \times 1 \text{ mm}^3$ for both the magnetic (Figs. 3 and 4) and the magnetoresistance studies (Figs. 5 and 6). The high temperature sintering causes a loss of oxygen and the magnetic properties of the sintered bars are similar to the powder argon annealed samples in Figs. 1(b) and 2(b). To make the sintered samples similar to the calcined powder ones we heat the sintered samples in O_2 for 60 h at 800–950 °C. Let us consider first the LMO in Fig. 3 where the conversion by oxygen anneal in Fig. 3(b) is only

FIG. 1. (a) Plots of magnetization σ (emu/gm) and reciprocal molar susceptibility $1/\chi_M$ vs T for (LMO) calcined powder. (b) Data for LMO after annealing in argon.

FIG. 3. (a) Magnetic data for the sintered bar sample of LMO. (b) Magnetic data for the oxygen annealed bar sample of LMO.

FIG. 4. (a) Magnetic data for the sintered bar sample of LYCMO. (b) Magnetic data for the oxygen annealed sample of LYCMO.

partly successful. In addition, the sharp drop in the $1/\chi_M$ at 250 K in the original sintered sample is probably due to a low percent inhomogeneous oxygen content. The CMR plots of the two LMO samples are shown in Fig. 5. The sintered sample in Fig. 5(a) has a very small response to an applied field of $H=40$ kOe and exhibits a large nonmetallic resistivity. Figure 5(b) shows LMO after the O_2 anneal. Now the

FIG. 5. (a) Resistivity as a function of T at $H=0$ and $H=40$ kOe for the sintered LMO bar in Fig. 3(a). The percentage change in magnetoresistance at 100 K is about 5%. (b) Resistivity vs T at $H=0$ and $H=40$ kOe for oxygen annealed LMO in Fig. 3(b). The CMR maximum for $T=200$ K is 100%. The CMR can be calculated from ρ ($\rho_{H=0} - \rho_{H=40 \text{ kOe}} / \rho_{H=40 \text{ kOe}}$). The CMR extended down to low temperature is probably due to a canted or mixed magnetic structure that remains after annealing.

FIG. 6. (a) Resistivity vs T for sintered LYCMO at $H=0$ and $H=40$ kOe in Fig. 4(a). The CMR is about 2500% at 150. (b) Resistivity vs T for oxygen annealed LYCMO at $H=0$ and $H=40$ kOe in Fig. 4(b). The CMR is about 300% at 2.

resistivity has dropped to $2 \Omega \text{ cm}$ at 100 K compared to $10^6 \Omega \text{ cm}$ before the O_2 anneal. The maximum CMR for the annealed LMO is about a 100% change at $T_c \approx 200$ K. The CMR measurements for LYCMO are given in Figs. 6(a) and 6(b) where the CMR is 2400% at 150 K for the sintered sample and 300% after the O_2 anneal. If the CMR depends on short range order clusters⁴ with polaron formation⁸ or hopping,⁹ the raising of T_c decreases these effects.

Single-crystalline and nontextured polycrystalline thin films of $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_{3-\delta}$ (LPMO) and $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3-\delta}$ (LCMO) have been prepared by pulsed laser deposition and by magnetron sputtering, respectively. The oxygen deficiency δ of the samples was controlled by heat treatments under defined oxygen pressure. For $\delta \approx 0$, the polycrystalline as well as the single-crystalline films are ferromagnetic metals with Curie temperatures T_c of 220–270 K. At low temperatures $T \ll T_c$, the polycrystalline LCMO films show a negative magnetoresistance ratio (MR) at $T=20, 77$, and 180 K of -30% , -20% , and -8% , respectively, for a field of 1.5 kOe. At 20 K, around 200 Oe, the field sensitivity is as high as $-0.5\% (\text{Oe})^{-1}$. A possible mechanism for this phenomenon is the spin-polarized tunneling through grain boundaries. For the single-crystalline films, the change of δ from 0 to about 0.1 has a similar effect as changing the doping level x from 0.3 to 0.1, namely, a transition from a ferromagnetic metal to a ferromagnetic insulator. By variation of δ , the low-temperature resistivity of these samples can be controlled within many orders of magnitude. The negative MR of oxygen-deficient single-crystalline LPMO and LCMO films was found to be as large as -20% at $T=0.2T_c$. © 1998 American Institute of Physics. [S0021-8979(98)38111-6]

Manganese oxides $(\text{R}^{3+})_{(1-x)}(\text{A}^{2+})_x\text{MnO}_3$ ($\text{R}=\text{La}$ or rare earth metals, $\text{A}=\text{Ca}, \text{Sr}, \text{Ba}, \text{Pb}$, $x=0.2-0.4$) have been intensively studied as a colossal magnetoresistance effect (CMR) is observed near the ferromagnetic ordering of the Mn spins.¹ The Curie temperature (T_c) is associated with a metal-insulator transition. Recently, polycrystalline samples were found to exhibit large magnetoresistance in a temperature range $T < T_c$, that appears in low magnetic fields and therefore is a step towards practical application of these materials.² The transport process of carriers through the structurally and magnetically disordered grain boundary is under investigation.³⁻⁵

The properties of these manganese oxides with perovskite structure strongly depend on the oxygen content that influences the carrier density and the magnetic ordering. Spin-glass behavior has been reported for oxygen deficient samples.⁶ There is, however, a lack of systematic investigations elucidating the dependence of the magnetic and transport properties on the oxygen content.

The aim of our work was to investigate the low-field MR effect in polycrystalline thin films at $T < T_c$. A further intention was to study the influence of oxygen deficiency on the magnetotransport at low temperatures.

Single-crystalline films of $\text{La}_{0.7}\text{M}_{0.3}\text{MnO}_{3-\delta}$ ($\text{M}=\text{Ca}, \text{Pb}$) were prepared on LaAlO_3 (100) substrates by pulsed

laser deposition and by radio-frequency magnetron sputtering, respectively. Nontextured polycrystalline films were grown on MgO and Y-stabilized ZrO_2 (YSZ) substrates by magnetron sputtering. The oxygen deficiency δ was controlled by heat treatments at 300–900 °C under an oxygen pressure of 10^{-3} – 10^{-2} Pa. The structure of the films was investigated by x-ray diffraction including pole figure measurements. Magnetic and magnetotransport measurements were carried out in a Lake Shore susceptometer and in a superconducting quantum interference device magnetometer. The resistance R of the samples was measured in dependence on temperature and magnetic field H , up to 70 kOe, by the usual four-probe technique. The magnetoresistance ratio is determined as $\text{MR}=[R(H)-R(0)]/R(0)$.

In contrast to single crystals and single-crystalline films of stoichiometric $\text{La}_{0.7}\text{M}_{0.3}\text{MnO}_3$ ($\text{M}=\text{Sr}, \text{Ca}, \text{Ba}, \text{Pb}$), polycrystalline films^{5,7} and ceramic samples² exhibit considerable magnetoresistance at temperatures far below T_c . This effect occurs in low magnetic fields and increases with decreasing temperature as shown in Fig. 1 for a polycrystalline $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ film grown on YSZ. The most pronounced resistance drop appears in small fields $H < 500$ Oe (inset of Fig. 1). The coercive field of this film is about 100 Oe. The increased slope of MR vs H for the 160 K curve, compared with that of the low temperature curves, for fields $H > 10$ kOe is attributed to the suppression of thermally activated spin fluctuations (i.e., the CMR effect near T_c).

The charge transport in polycrystalline manganites is af-

FIG. 1. Magnetoresistance ratio vs magnetic field for a polycrystalline $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3-\delta}$ film measured at various temperatures. Inset: low-field range $H < 2$ kOe, expanded.

ected by grain boundaries because of their structural and magnetic disorder. As a possible transport mechanism, spin-polarized tunneling (SPT) of electrons through the grain boundaries was proposed.² The spin-polarization factor of the density of states at the Fermi level should be very high in these compounds.^{8,9} The tunneling probability will be restricted by a nonparallel orientation of the magnetization of adjacent grains. Gupta *et al.*⁵ have shown by Kerr microscopy that grains of several microns in size often coincide with the magnetic domains and are characterized by their individual switching field in the magnetization process. Our films show a nearly complete saturation of magnetization at fields of 3–5 kOe for $T \ll T_c$. Therefore, the main part of the resistance drop in $H < 2$ kOe (Fig. 1) is attributed to SPT. Magnetic scattering by magnetic disorder in the grain-boundary region could be responsible for the further decrease of resistance observed in an increasing magnetic field $H > 5$ kOe (Fig. 1). This decrease is much stronger than that found for single-crystalline samples.

One aim was to check if the observed MR behavior in low magnetic fields is compatible with spin-polarized tunneling. In some field interval $0 < H < H_1$, a linear dependence of the MR on the square of the normalized magnetization was found for several polycrystalline films: $\text{MR}(H) = a + b [M(H)/M(50 \text{ kOe})]^2$ (Fig. 2). For the sample of Fig. 2, we find $H_1 = 1.2$ kOe, $a \approx 0$, and $b = -0.21$. This is consistent with the first term in the high temperature expansion of the MR for SPT given by Hwang,²

$$\text{MR}(H, T) = -JP/(4kT)[m(H, T)^2 - m(0, T)^2], \quad (1)$$

where J is the intergrain exchange constant, P is the spin-polarization factor, and m is the magnetization normalized to the saturation value.

In order to examine the temperature dependence of the low-field contribution, MR^* , to the magnetoresistance, we extrapolated the $\text{MR}(H)$ curve from $H > 10$ kOe to zero field using a polynomial fit. The intersection point at the vertical axis ($H=0$) gives the value of MR^* . At low temperatures, $T < 0.1T_c$, a saturation of MR^* is found. With increasing

FIG. 2. Magnetoresistance ratio vs square of magnetization normalized to the value measured at $H = 50$ kOe, for the sample of Fig. 1.

temperature, MR^* drops rapidly. MR^* proportional to T^{-1} , according to Eq. (1), is only observed for a small temperature interval around $1/2T_c$.

If the magnetic field is increased above technical saturation, the MR grows continuously without a significant increase of magnetization (Fig. 2). [Because of a not exactly known diamagnetic contribution of our substrates, small changes of film magnetization in high fields ($< 10\%$) cannot be detected.] This increase in MR is ascribed to an ordering of the spins in the grain-boundary region by the high field. Such an ordering should influence the resistance of the grain boundary via the double-exchange mechanism,⁵ but it has a small effect on the total magnetization.

A considerable low-temperature MR arises in single-crystalline films of $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3-\delta}$ and $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_{3-\delta}$ after the oxygen content has been reduced ($\delta > 0$) by annealing. This low-temperature MR is small in low magnetic fields and does not saturate in magnetic fields up to 50 kOe (Fig. 3, for a LPMO sample). In the inset of Fig. 3, three $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_{3-\delta}$ films with reduced oxygen content [$\delta(A) < \delta(B1) < \delta(B2)$, prepared from one original sample] are characterized by their temperature dependence of resistance. The curves resemble those of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ samples with a doping level of $x = 0.1-0.3$.¹⁰ This should be expected because the oxygen deficiency reduces the Mn^{4+} -to- Mn^{3+} concentration ratio. The insulating behavior of the oxygen-deficient samples at low temperatures can be qualitatively discussed using the magnetic localization model of Viret *et al.*¹¹ Recently, these authors suggested a random magnetic potential

$$kT_0 = 171\alpha^3 U_m [1 - (M/M_s)^2] v \quad (2)$$

to be responsible for charge carrier localization, where α is the inverse localization length, U_m the Hund's rule splitting energy, v the cell volume, and M_s the collinear saturation magnetization. In this model, the occurrence of spin canting should lead to insulating behavior at low temperatures when M/M_s has a constant value smaller than one. Under the assumption that spin canting is the only reason for the reduced saturation magnetization measured for our oxygen-deficient

FIG. 3. Magnetoresistance ratio and magnetization vs field for an oxygen-deficient single-crystalline $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_{3-\delta}$ film ($T_c=200$ K) at $T=77$ K. Inset: resistance vs temperature of three pieces, A, B1, and B2, of an original $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$ sample, annealed in different oxygen atmospheres resulting in $\delta(A)<\delta(B1)<\delta(B2)$.

films, we estimate $M/M_s(5\text{ K})\approx 0.85$ for sample B2 from the values of saturation magnetization measured before and after the desoxygenation. However, it cannot be excluded that magnetic inhomogeneity in the sense of a mixture of ferromagnetic and nonferromagnetic regions leads to the reduced saturation magnetization and the insulating low-temperature behavior of our oxygen deficient samples. The resistance data for the low-temperature insulating state of B1 and B2 can be well fitted to $R(T)=R_\infty \exp(T_0/T)$. This does not agree with the variable range hopping (VRH) mechanism of Ref. 11. But the idea of magnetic localization should not be restricted to this special kind of hopping mechanism and therefore is expected to apply to our data.

In Fig. 4, the temperature dependence of the MR of several oxygen-deficient samples is shown. The MR peak near T_c broadens substantially for the $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_{3-\delta}$ samples B1 and B2 which therefore exhibit a considerable MR far below T_c . In the inset of Fig. 4, the curves of two $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3-\delta}$ samples [$\delta(S)\approx 0$, $\delta(S1)\approx 0.07$] are shown for comparison. The MR of the oxygen deficient sample S1 has a second maximum of MR at a temperature $T_1<T_c$. It is possible that for B1 and B2 this low-temperature maximum of the MR is there, but it overlaps the main peak around T_c . The estimated peak temperature T_1 for B1 and S1 nearly equals that of the minimum of R vs T . Further work should clarify if the low temperature maximum of the MR at T_1 is associated with a canted spin structure or with magnetic inhomogeneity.

In summary, we have examined the magnetoresistance and the magnetization of single-crystalline and polycrystalline films of $\text{La}_{0.7}\text{M}_{0.3}\text{MnO}_{3-\delta}$ ($M=\text{Ca}, \text{Pb}$) in the ferromagnetic state. For the polycrystalline samples, the value of the large negative low-field MR was found to saturate at low temperatures and then to drop rapidly with increasing temperature. A quadratic correlation with the magnetization, MR

FIG. 4. Magnetoresistance ratio vs temperature for the three single-crystalline $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_{3-\delta}$ films from Fig. 3. Inset: magnetoresistance ratio vs temperature for two single-crystalline $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_{3-\delta}$ films with $\delta(S)\approx 0$, $\delta(S1)\approx 0.07$.

proportional to $(M/M_s)^2$, was observed in a field range $0<H<H_1$, a field value near the saturation field of magnetization. Single-crystalline films undergo a second metal-to-insulator transition at low temperatures, after their oxygen content has been reduced by an annealing procedure. They show a large negative MR at $T\ll T_c$, that does not saturate up to $H=50$ kOe. This MR effect due to oxygen deficiency may be important for the understanding of the MR of oxygen-deficient polycrystalline material.

Fully relativistic theory for the magnetic extended x-ray absorption fine structure

D. Ahlers^{a)} and G. Schütz

Lehrstuhl für Experimentalphysik II, Universität Augsburg, Memmingerstrasse 6, D-86135 Augsburg, Germany

V. Popescu and H. Ebert

Institut für Physikalische Chemie, Universität München, Theresienstrasse 37, D-80333 München, Germany

A fully relativistic theoretical description of the magnetic extended x-ray absorption fine structure (MEXAFS) is presented that has been set up within the framework of relativistic multiple scattering theory on the basis of the Dirac equation for spin-polarized, magnetic solids. The multiple scattering processes in the final state are treated using the scattering path expansion technique for finite atomic clusters. Results of the approach for the Fe *K* and the Gd *L* edges are presented and are compared with experiment. An analysis of the theoretical spectra clearly shows that the MEXAFS spectra can be interpreted on the basis of the so-called sum rules in a way completely analogous to the case of near-edge x-ray magnetic circular dichroism. This means that the *K*- and *L*₁-edge spectra directly reflect the orbital polarization of the final states with *p* character. The *L*_{2,3}-edge spectra, on the other hand, give, after suitable superposition, access to the spin and orbital polarization of the *d* states.

I. INTRODUCTION

The magnetic extended x-ray absorption fine structure (MEXAFS), the analogon to normal EXAFS when using circularly polarized radiation, has become an interesting technique to study the magnetic short range order around the absorbing atom in an element selective manner.¹ As for x-ray magnetic circular dichroism (XMCD) in the near-edge region, the MEXAFS originates from the interplay of spin-polarization and spin-orbit coupling. On this basis a phenomenological model for MEXAFS has been developed by Schütz and Ahlers by introducing a spin-dependent back-scattering term to conventional EXAFS.² A more profound treatment of MEXAFS using nonrelativistic multiple scattering theory for a finite cluster of atoms has been developed by Brouder and co-workers^{3,4} as well as by Ankudinov and Rehr.^{5,6} In both cases, however, spin-orbit coupling and/or spin polarization are considered only in an approximate way. We present results from a fully relativistic description of MEXAFS based on relativistic multiple scattering theory for magnetic systems.⁷ These spectra are discussed on the basis of the so-called sum rules.

II. THEORETICAL FRAMEWORK

The basis for the calculation of the x-ray absorption coefficient $\mu^\lambda(\omega)$ presented below is the conventional expression⁸

$$\mu^{\lambda}(\omega) \propto \sum_{iocc} \langle \Phi_i | X_{q\lambda}^\times \mathcal{T} G^+(E_i + \hbar\omega) X_{q\lambda} | \Phi_i \rangle \Theta(E_i + \hbar\omega - E_F). \quad (1)$$

Here the wave function Φ_i of the involved initial core states are solutions to the Dirac equation for a spin-dependent potential.⁹ The electron photon interaction operator $X_{q\lambda}$ describes the coupling of the electronic current density operator to the vector potential $\mathbf{A}_{q\lambda}$ of light with wave vector \mathbf{q} , frequency ω , and polarization λ . The final states are represented by the Green's function:⁸

$$G^+(\mathbf{r}_n, \mathbf{r}_n, E) = \sum_{\Lambda\Lambda'} Z_\Lambda(\mathbf{r}_n, E) \tau_{\Lambda\Lambda'}^{nn} Z_{\Lambda'}^\times(\mathbf{r}_n, E) - \sum_{\Lambda} Z_\Lambda(\mathbf{r}_n, E) J_\times(\mathbf{r}_n, E), \quad (2)$$

with the wave functions Z_Λ and J_Λ [$\Lambda = (\mu, \kappa)$] being the regular and irregular, respectively, solutions to the Dirac equation. Finally, the quantity $\tau_{\Lambda\Lambda'}^{nm}$ is the so-called scattering path operator that consistently represents all multiple scattering events within a solid and has to fulfill the self-consistency condition:

$$\underline{T}^{nm} = \underline{t}^n \delta_{nm} + \underline{t}^n \sum_{k \neq n} \underline{G}^{nk} \underline{T}^{km}, \quad (3)$$

where \underline{t}^n is the single site *t* matrix for site *n* and \underline{G}^{nk} is the free electron propagator connecting sites *k* and *n*. For the EXAFS region it is sufficient to account only for multiple

^{a)}Electronic mail: ahlers@physik.uni-wuerzburg.de

scattering paths within the vicinity of the absorbing atom. Therefore it is possible to reduce the problem to a cluster of limited size. In that case Eq. (3) can be inserted repeatedly into itself, yielding for $\tau_{\Lambda\Lambda}^n$ in Eq. (2) a series of scattering paths with increasing complexities.

From these considerations it is obvious that there is no fundamental difference for the x-ray absorption in the near edge and EXAFS regions. Therefore the question arises as to whether the interpretation of the XMCD spectra with the so-called sum rules also holds for the EXAFS region. As derived by Igarashi and Hirai,¹⁰ Carra *et al.*¹¹ and Thole *et al.*,¹² the sum rules can be expressed as

$$\frac{\int \mu_c(K)/E dE}{\int \mu_0(K)/E dE} = \frac{3}{N_{hp}} \langle l_z \rangle_p, \quad (4a)$$

$$\int [\mu_c(L_3) - \mu_c(L_2)] dE = \frac{3N}{4N_{hd}} (\langle \sigma_z \rangle_d + 7 \langle T_z \rangle_d), \quad (4b)$$

$$\int [2\mu_c(L_3) + \mu_c(L_2)] dE = \frac{3N}{2N_{hd}} \langle l_z \rangle_d. \quad (4c)$$

Here $\mu_c(X)$ ($X=K, L_2, L_3$) are the circular dichroism spectra, i.e., they give the difference in absorption for left and right circularly polarized radiation at the various edges. N is the sum of the energy integrals for all partial absorption spectra and N_{h1} is the number of holes for angular momentum character 1. The expectation values $\langle \sigma_z \rangle$ and $\langle l_z \rangle$ give the spin and angular momentum of the absorber atom and $\langle T_z \rangle$ is a measure for the asphericity of the spin magnetization that can be neglected in most cases.

III. EXPERIMENTAL DETAILS

The experiments were performed at the R6Mo II station at the HASYLAB in Hamburg using the two beam transmission mode. The estimated intensity of the beam monochromatized by a Si(111) double crystal was 10^7 – 10^8 photons/s eV with a circular polarization of 60%–70%. The spectra were sampled alternating the external magnetic field every second at each energy point. A magnetic field of $B_0 = 0.2$ T was applied and the Gd sample was cooled to 150 K.

The measured quantities of the experiment are the spin-averaged absorption coefficient $\mu_0(E) = \frac{1}{2}[\mu^+(E) + \mu^-(E)]$ and the corresponding dichroic signal $\mu_c(E) = \frac{1}{2}[\mu^+(E) - \mu^-(E)]$ for parallel (+) and antiparallel (–) orientation of the photon “spin” to the spin of the majority-like electrons in the sample. The spin-averaged EXAFS spectra $\chi_0(E) = [\mu_0(E) - \mu_{\text{atom}}(E)]/\mu_{\text{atom}}(E)$ have been deduced in the conventional way by subtracting the free atom absorption μ_{atom} . The MEXAFS spectra are denoted as the difference $\chi_c(E) = [\mu_c(E)/\mu_{\text{atom}}(E)]/(P_c \cdot M_z)$. They are rescaled for full circular polarization $P_c = 1$ and complete alignment of the sample magnetization along the photon k vector $M_z = 1$.

IV. APPLICATION TO Fe AND Gd

In Fig. 1 we compare the results of our theoretical calculations and the experimental spectra for the Fe K edge in body-centered-cubic (bcc) Fe. The top panel gives the con-

FIG. 1. X-ray absorption spectra at the K edge of Fe. Top: absorption for unpolarized radiation $\chi_0(E)$. Bottom: dichroic signal $\chi_c(E)$.

ventional EXAFS $\chi_0(E)$ with the characteristic oscillations in the high energy region. In the lower panel the magnetic EXAFS signal $\chi_c(E)$ is shown. The dichroic signal is about three orders of magnitude smaller than the normal EXAFS and therefore even less pronounced than in the XANES region. For the calculations a cluster of eight neighboring shells with 113 atoms and a radius of 6.4 Å was used. The path expansion considered paths with up to two scattering centers and a total length of 7.5 Å. The orbital momentum expansion was carried to $l_{\text{max}} = 7$. In both cases the overall agreement with the experimental data is very satisfying. All significant features of the spectra are reproduced by the theoretical calculations in a correct way. Here one has to note that $\chi_c(E)$ is obtained in quantitative agreement without any adjustable parameter. The overestimation of the magnitude of the oscillations at very high energies in the normal EXAFS can be explained by the fact that lattice vibrations are not yet incorporated into our model. The smaller dichroic signal at low energies is caused by the limited size of the cluster used. In particular longer and high order scattering paths contribute to the signal in this region.

In Fig. 2 the results at the Gd L edges in hexagonal-close-packed (hcp) Gd are compared with experiment. While the left panel shows the conventional EXAFS, the dichroic signal is given in the right. The amplitude of the dichroic signal at the L edges is only one order of magnitude smaller than the normal EXAFS and hence much larger than at K edges. A cluster of six shells with 38 atoms was used in the calculation considering all paths with up to two scattering centers and a total length of 7 Å. The orbital momentum was again limited to $l_{\text{max}} = 7$. There is a small underestimation of the EXAFS oscillations in the calculated results at energies below 130 eV. Also the dichroic signal at the L_1 edge is larger in the experiment than was predicted by the calculation. Nevertheless all features in the spectra are reproduced in a very satisfying way. The pronounced features at about 150 eV are attributed to so-called magnetic multiple electron excitations (MMEEs)¹³ and can obviously not be reproduced by our model.

FIG. 2. X-ray absorption spectra at the $L_{2,3}$ edge of Gd. Left: absorption for unpolarized radiation $\chi_0(E)$. Right: dichroic signal $\chi_c(E)$.

The theoretical approach presented above opens the way for a very detailed interpretation and analysis of the MEXAFS spectra. Thinking of the absorption as a local process at the absorbing atom the primary physical information to be read from these spectra can be obtained on the basis of the sum rules. As was demonstrated for the XANES region by various authors,^{14,15} the differential form of the sum rules for the K and L_1 edges allows one to connect $\chi_c(E)$ to the orbital polarization $d\langle l_z \rangle_p/dE$ of the p states.

In Fig. 3 the orbital polarization is shown together with the experimental data for the Fe K and the Gd L_1 edges. It is obvious that all the prominent features of the spectra can be

FIG. 3. Orbital- $d\langle l_z \rangle_p/dE$ polarization for the p states of Fe and Gd compared with the dichroic signal.

FIG. 4. Spin- $d\langle \sigma_z \rangle_d/dE$ and orbital- $d\langle l_z \rangle_d/dE$ polarization for the d states of hcp Gd compared with those extracted from the experimental data using Eq. (4).

related to the structure of the orbital polarization. This gives strong evidence for the applicability of the K - and L_1 -edge sum rule even up to very high energies.

In Fig. 4 the theoretical spin and orbital polarizations as extracted by Eq. (4) are compared with the same quantity determined from the experimental data. The strong peak in $d\langle l_z \rangle_d/dE$ is related to the MMEE mentioned above. Due to the spectroscopic ground state $^8S_{7/2}$ an orbital polarization of the $5d$ states is introduced only by spin-orbit and exchange effects and adds $\approx 0.25\mu_B$ to the total magnetic moment of $7.64\mu_B$.¹⁶ Accordingly, the spin polarization is about 10 times as large as the orbital contribution. Apart from the deviation in the spin polarization at about 120 eV the agreement is satisfactory. In spite of the uncertainty for the orbital polarization because of the limited experimental resolution these results give a clear indication that the sum rules are not limited to the circular dichroism in the XANES region.

The spin-dependent extended x-ray absorption fine-structure (EXAFS), i.e., the magnetic counterpart to the conventional EXAFS when using circularly polarized light in a ferro(i)magnet, was measured at the $L_{2,3}$ edges of Eu in $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ and EuO and at the K edge of CrO_2 . Complementary near-edge x-ray magnetic circular dichroism measurements at the O K edge were made to directly access the oxygen magnetization. It is shown that there is an influence of the nearly nonmagnetic oxygen atoms on the magnetic EXAFS depending on the local symmetry of the crystal as well as on the relative direction of the magnetic moments of neighboring atoms. The observed influences at distances corresponding to the oxygen neighbors in EuO are interpreted as the harmonic focusing effect, i.e., over-next magnetic neighbors behind the oxygen are responsible for the observed contributions. © 1998 American Institute of Physics. [S0021-8979(98)51811-7]

I. INTRODUCTION

Since the first observation of a magnetic contribution to the extended x-ray absorption fine structure (EXAFS),¹ spin-dependent EXAFS (SPEXAFS), this new spectroscopic method has evolved to provide new attractive possibilities to study the magnetic short range order in ferro(i)magnetic materials.² From a variety of systematic studies the relative amplitude of the dichroic contribution is found to be directly proportional to (a) the spin polarization $\langle\sigma_z\rangle$ of the photoelectron ejected after absorption of a circularly polarized photon and (b) the average spin moment of the neighboring coordination shells. Since the spin polarizations $\langle\sigma_z\rangle(L_3) = 0.25$ and $\langle\sigma_z\rangle(L_2) = -0.50$ are related by a factor of -2 , the ratio between the $L_{2,3}$ -edge dichroic signals can be used to test the polarization dependence of the SPEXAFS model. At the K edge the spin polarization $\langle\sigma_z\rangle(K) \sim 0.03$ is very small since there is no spin-orbit coupling in the initial state. The correlation of the SPEXAFS to the spin moment can be expressed in terms of the amplitude maxima of the Fourier transform (FT).³

$$\frac{1}{\langle\sigma_z\rangle} \frac{\max\{\text{FT}[\chi_c(k)]\}}{\max\{\text{FT}[\chi_0(k)]\}} = +2.4(2)\% \mu_S(\mu_B), \quad (1)$$

where μ_S is the average spin moment of the neighboring shell. In this article we report on new precise measurements of the $L_{2,3}$ edges of Eu in EuO and $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ and the K edge of Cr in CrO_2 focusing on the role of the oxygen next neighbors in the SPEXAFS signal.

II. EXPERIMENTAL DETAILS

The experiments in the hard x-ray regime were performed at the RöMo II station at the HASYLAB in Hamburg using the two beam transmission mode. For EuO a magnetic field of $B_0 = 0.5$ T was applied and the sample was cooled to 10 K. $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ and CrO_2 were measured at room tempera-

ture with $B_0 = 0.25$ T. The O K edges of $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ and CrO_2 were recorded at the SX700/III station at BESSY using the total electron yield technique. The same mode was used for the O K edge of EuO at the Dragon beamline at the ESRF. The sample conditions were identical to those of the hard x-ray experiments. In the experiment the measured quantities were the spin-averaged absorption coefficient $\mu_0(E) = \frac{1}{2}[\mu^+(E) + \mu^-(E)]$ and the corresponding dichroic signal $\mu_c(E) = \frac{1}{2}[\mu^+(E) - \mu^-(E)]$ for parallel (+) and antiparallel (−) orientations of the photon “spin” to the spin of the majoritylike electrons in the sample. The spin-averaged EXAFS spectra $\chi_0(k) = [\mu_0(k) - \mu_{\text{atom}}(k)]/\mu_{\text{atom}}(k)$ were deduced with the free atom absorption μ_{atom} . The SPEXAFS spectra are denoted as the difference $\chi_c(k) = [\mu_c(k)/\mu_{\text{atom}}(k)]/[P_c \cdot M_z]$. They are rescaled for full circular polarization $P_c = 1$ and complete alignment of the magnetization $M_z = 1$. For the Fourier transformation all spectra were weighted with k^1 and folded with a Kaiser-Bessel window.

III. RESULTS AND DISCUSSION

A. The garnet $\text{Eu}_3\text{Fe}_5\text{O}_{12}$

Garnets form an overall cubic lattice [space group $Ia\bar{3}d(O_h^{12})$]. The metallic ions are distributed over three different lattice sites: two octahedral sites A (Fe^{3+}), three tetrahedral sites D (Fe^{3+}), and then three dodecahedral sites C (Eu^{3+}). All ions are coupled by superexchange via oxygen atoms in general positions H . The A and D lattices are coupled strongly antiparallel, whereas the A and C lattices are weakly parallel. In the upper panel of Fig. 1 the spin-averaged $\chi_0(k)$ and the spin-dependent $\chi_c(k)$ signals are presented. Since the Eu L_3 edge at 6977 eV is followed by the Fe K edge at 7111 eV, the usable range of the L_3 edge $\chi_0(k)$ is very short. The ratio of -2 is conserved in the SPEXAFS, indicating that the orbital moment does not contribute to the magnetic scattering. One immediately notices that the normal and magnetic signals differ drastically in the

FIG. 1. Top: The $\chi_0(k)$ (dotted line) and $\chi_c(k)$ (solid line) spectra of Eu at the $L_{2,3}$ edges. Bottom: The FT [$\chi_0(k)$] (dotted line) and FT [$\chi_c(k)$] (solid line) spectra. Due to the interference of the Fe K edge the transformation interval for χ_0 is very short. Since the photoelectron polarization at the K edges is small, one can neglect this influence when transforming χ_c .

frequency of their oscillation. Looking at the Fourier transforms in Fig. 1 this observation becomes more clear. Typical for oxides, the FT of $\chi_0(k)$ is dominated by the strong first maximum resulting from the next oxygen neighbors. The second peak, due to the limited resolution at the L_3 edge that is only visible in the L_2 FT, indicates the positions of three next-neighbor shells occupied by 2 Fe on D , 4 Fe on A , 4 Fe on D , and 4 Eu on C sites, respectively. All peaks appear at slightly smaller distances as is expected from the crystal structure. In the EXAFS analysis such a shift is connected with the k dependence of the scattering phase and is normally in the order of 0.3–0.5 Å. The FT spectra have not been corrected for this shift since such a correction for the SPEXAFS would be arbitrary. In the FT of the $L_{2,3}$ SPEXAFS the prominent oxygen peaks have vanished due to an increase in the maxima at 3.3 and 5.7 Å. By forming the ratio of the FT lines at 3.1 Å, applying the formalism of Eq. (1), one obtains an estimation of the average spin-moment buildup in the three unresolvable shells of $\mu_{sp} = 4.9\mu_B$. This is somewhat larger than the theoretical sum of the individual moments of $4.1\mu_B$, but can be explained by the differences in the distance of these shells. Nevertheless the results presented indicate that the strength of the SPEXAFS is correlated to the magnetic moment of the backscattering atoms.

B. The half-metal CrO_2

Chromium dioxide belongs to a class of transition-metal dioxides with a rutile structure and a predicted half-metallic character.⁴ Ferromagnetic ordering sets in at $T_c = 392$ K, the coupling mediated by the O^{2+} ions via superexchange. The left panels of Fig. 2 show the spin-averaged $\chi_0(k)$ and spin-dependent $\chi_c(k)$ measurements at the Cr K edge. Note that due to the small photoelectron polarization $\langle\sigma_z\rangle \sim 1.2\%$ the dichroic signal is extremely small. As for the garnet, two different frequencies of oscillation are observed which is confirmed in the FT spectra in the right hand panels of Fig. 2. The spin-averaged spatial distribution FT[$\chi_0(k)$] is domi-

FIG. 2. The spin-averaged (top) and the dichroic signal (bottom) at the Cr K edge in CrO_2 (left). The corresponding Fourier transforms are shown at the right.

nated by three peaks originating from 6 O (1.4 Å), from 6 Cr (2.5 Å), and from 16 O (3.2 Å) neighbors, respectively. In the spin-dependent distribution FT[$\chi_c(k)$] only one major peak is visible at 2 Å, and it is shifted by almost 0.5 Å towards smaller distances than is the Cr peak in the EXAFS. That only one peak remains clearly indicates that this peak must be attributed to the Cr shell. Applying Eq. (1) to these Cr lines gives a magnetic moment of $2.0\mu_B$, in good agreement with theoretical predictions.⁴ The reason for the large shift, at this size it has not been seen before in a comparison between EXAFS and SPEXAFS might be due to the band-like character of the magnetism of CrO_2 . The strong delocalization of the magnetic electrons is surely influencing the spatial distribution of the SPEXAFS.

C. The chalcogenide EuO

The divalent europium chalcogenides are very representative of simple isotropic Heisenberg magnets. In these semiconductors the magnetic Eu^{2+} ions (ground state $^8S_{7/2}$) form simple face-centered-cubic (fcc) lattices. Two coupling mechanisms are considered for EuO: the direct interaction between the Eu neighbors and the coupling of the Eu ions via superexchange of the oxygen. The extracted spin-averaged $\chi_0(k)$ (dotted line) and the spin-dependent $\chi_c(k)$ signal (solid line) are presented in the top panel of Fig. 3. Looking at the frequency of the oscillations, a difference is not seen here. The FT for EuO, displayed in the bottom panel of Fig. 3, supports this finding. Since the spectra were recorded at 10 K, damping by the Debye–Waller factor, representing lattice vibrations, is almost negligible, thus extending the L_3 EXAFS far into the L_2 -edge region. This effect becomes visible at the L_2 -edge FT in the large unexpected peak at about 1.6 Å. The first line at 2.2 Å corresponds to the first oxygen coordination shell. The second line at 3.4 Å represents the next Eu neighbors. An approximation of the average moment of the neighboring Eu shell using Eq. (1) yields $6.2\mu_B$. The same procedure for the oxygen peak, however, leads to the unrealistic value of $5.9\mu_B$. We believe that the contributions at the oxygen sites are caused by a focusing effect. In EXAFS analysis this well known phenomenon de-

FIG. 3. Top: The $\chi_0(k)$ (dotted line) and $\chi_c(k)$ (solid line) spectra of Eu at the $L_{2,3}$ edges. Bottom: The FT [$\chi_0(k)$] (dotted line) and FT [$\chi_c(k)$] (solid line) spectra. The unexpected lines at 1.6 Å in the L_2 -edge FT are tails from the EXAFS at the L_3 edge.

scribes the fact that those shells directly behind closer neighbors appear stronger in the Fourier analysis than that estimated by their simple distance.⁵ The outgoing photoelectron wave experiences the potential of the first neighbor as a kind of a lens, focusing it on the over next neighbor. This way the effective amplitude is enhanced. In the case of EuO we have a higher harmonic of this effect. A wave corresponding to the oxygen distance effectively interferes also when scattered at the Eu neighbor behind the oxygen, the distance being twice as large. So if one imagines the wave with a knot at the oxygen site, one sees the full spin moment of the Eu atom in the SPEXAFS at the oxygen position.

D. The oxygen measurements

Figure 4 shows the near-edge x-ray magnetic circular dichroism (XMCD) spectra of the oxygen K edge in $\text{Eu}_3\text{Fe}_5\text{O}_{12}$, EuO , and CrO_2 . The spin-averaged absorption $\mu_0(E)$ (left) is characterized by the typical narrow first peak and a broad second peak which for the garnet is almost twice as high as that for EuO . The absorption profile for CrO_2 is even more complex. Since CrO_2 is not stable, there is a surface contamination with Cr_2O_3 . The characteristic line at 531 eV, however, is only visible for CrO_2 and can be used to estimate the concentration. The amplitude of the spin-dependent signal $\mu_c(E)$ (right) is in all cases very small. In the Eu compounds the dichroic oxygen signal displays a very complex structure with effects of the order of only 0.5%. There are two dispersive structures visible at 530 and 536 eV, the former with the same sign as that for $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ and EuO , the latter, however, with the opposite sign. Possibly this is an effect of the ferrimagnet $\text{Eu}_3\text{Fe}_5\text{O}_{12}$, where the magnetic moments neighboring the oxygen cite are coupled antiparallel. The oxygen K -edge dichroism in CrO_2 is much simpler and amounts to 1%. Only one dispersive structure is found, indicating that the coupling mechanism is less complex. Although a final interpretation of the oxygen spectra is still to be made, there is no hint about a particular large moment in the case of EuO .

FIG. 4. The spin-averaged (left) and the dichroic signal (right) at the O K edge in $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ (top), EuO (center), and CrO_2 (bottom). The spectra are normalized to 1 for the first peak in the spin-averaged absorption. The structure of the dichroic signal is extremely complex.

IV. CONCLUSION

New results of magnetic EXAFS measurements on magnetic oxides were presented. The contribution of the oxygen to the dichroic signal was thereby very different for the different compounds. In $\text{Eu}_3\text{Fe}_5\text{O}_{12}$ there was no contribution by the oxygen to the SPEXAFS at all. In the half-metal CrO_2 the next magnetic neighbor shell was shifted twice as much towards smaller distances than the corresponding electronic shell, indicating an influence particular on the magnetic scattering phase. In EuO a strong peak occurs at the oxygen position, which cannot be explained by oxygen magnetization. We believe that we have shown that the focusing effect, well known in EXAFS analysis, gives a reasonable explanation of the observed phenomenon. Further experiments using Compton and neutron scattering to accurately determine spin and orbital moment distributions and theoretical calculations are needed to clarify the specific details of these phenomena.

The combination of x-ray magnetic circular dichroism (X-MCD) with anomalous small angle x-ray scattering (ASAXS) allows to determine size distributions and correlations lengths in the nanometer range of magnetic precipitates in granular systems. Results on an amorphous GdFe system with a pronounced perpendicular magnetic anisotropy are reported. Standard ASAXS measurements taken at the Fe *K* edge provide information on the electronic structure yielding a correlation maximum at 75 Å and an average particle radius of 6 Å. The magnetic scattering curves (MASAXS) were obtained at the corresponding Gd *L*_{3,2} edges. Their intensities can be explained by magnetic contributions to the anomalous scattering factors *f'* and *f''*. A change of sign in the MASAXS is observed between profiles taken at the *L*₃ and the *L*₂ edge and with the change of circular polarization as expected from X-MCD. © 1998 American Institute of Physics. [S0021-8979(98)24911-5]

I. INTRODUCTION

A fundamental understanding of magnetic microstructures is an outstanding challenge both in current research of magnetism and its technological applications. Thereby reliable information on the electronic and magnetic structure on a typical length scale of 1–100 nm is mandatory. Among other recent observations of novel phenomena like the occurrence of the GMR, quantum oscillations or the magnetic interface anisotropy in magnetic thin films or multilayered systems, the origin of the perpendicular magnetic anisotropy in granular thin GdFe films is in particular still an open problem.

An established technique to study size distributions and correlations of particles in the nm range is the small angle x-ray scattering (SAXS). Using tunable x rays with high brilliance being available at synchrotron sources the mode of contrast enhancement (anomalous SAXS=ASAXS) can be engaged, i.e., involving the element-specific anomalous scattering amplitude *f'*(*E*), which varies with energy by about 20% in the vicinity of absorption edges, thus providing more detailed structural information on multicomponent systems.

In a two-phase model the scattering contrast Δc in SAXS is given by $(n_1 \cdot f_1 - n_2 \cdot f_2)$ with *n_i*, *f_i* being the density and atomic scattering amplitudes of phase *i*. The cross section $d\sigma/d\Omega$ is proportional to Δc^2 which in the case of anomalous scattering can be related to $(n_1 = n_2)$

$$\frac{d\sigma}{d\Omega} \approx |f(E, Z)|^2 = |f_0 + f'(E) + if''(E)|^2, \quad (1)$$

with the atomic form factor $f_0 = Z$ (atomic number) and *f'* and *f''* being the additional anomalous contributions. *f'* and *f''* are connected to each other via a Kramers–Kronig relation, whence *f''* can be related to the absorption coefficient $\mu(E)$ via the optical theorem

$$f''(E) = \frac{mc}{4\pi e^2} \frac{E}{h} \mu(E). \quad (2)$$

The effect of x-ray magnetic circular dichroism (X-MCD), i.e., the dependence of the absorption of circular polarized x rays on the projection of the magnetization onto the photon propagation direction (\hat{e}_z) in ferromagnetic samples¹ occurs in the vicinity of inner-core absorption edges. Due to angular momentum conservation in the absorption process the photoelectron acquires both an expectation value of the spin $\langle \sigma_z \rangle$ and the orbital $\langle l_z \rangle$ momentum projected onto \hat{e}_z . It can therefore serve as a local probe for the spin and orbital polarization of the absorbing atom according to the principle of Pauli. $\langle \sigma_z \rangle$ amounts to –50% and +25% at the *L*₂ and *L*₃ edges, while $\langle l_z \rangle = +75\%$ at both *L*_{2,3} edges. X-MCD has become a powerful tool for the element-specific and symmetry-selective investigation of the local magnetic structure on an atomic scale. Applying magneto-optical sum rules,² it is possible to determine in certain cases spin and orbital moments separately. Beyond this local magnetic structure a spin-dependent contribution has been manifested in the extended x-ray absorption fine structure (EXAFS)

range (magnetic EXAFS=MEXAFS), too, which allows to study the magnetic short-range order in multicomponent systems even on a larger size scale up to 20 Å.

The potential of X-MCD, however, is not restricted to the study of absorption profiles. In principle every method used in spectroscopy or crystallography, where the absorption coefficient is involved, can be extended to its magnetic counterpart. Thus the basic idea of magnetic anomalous small angle x-ray scattering (MASAXS) is to achieve the contrast enhancement via the effect of X-MCD. As the dichroic signal depends on the projection of the local magnetization of the absorbing atoms onto \hat{e}_z the magnetic scattering curves reflect the size distribution and correlation lengths of the magnetic scattering precipitates. Given the magnetic absorption coefficient for parallel/antiparallel alignment of magnetic electrons relative to \hat{e}_z by $\mu^\pm(E) = \mu_0(E) \pm \mu_c(E)$ the corresponding scattering amplitudes $f'^\pm(E)$ and $f''^\pm(E)$ both acquire magnetic contributions $f'_c(E)$ and $f''_c(E)$, namely,

$$f'^\pm(E) = f'(E) \pm f'_c, \quad (3)$$

$$f''^\pm(E) = f''(E) \pm f''_c. \quad (4)$$

Inserting Eqs. (3) and (4) into Eq. (1) the magnetic cross section, i.e., the difference in scattered intensities for parallel and antiparallel orientation is given by

$$\left(\frac{d\sigma}{d\Omega}\right)^+ - \left(\frac{d\sigma}{d\Omega}\right)^- \approx 4(f_0 + f')f'_c + 4f''f''_c. \quad (5)$$

II. EXPERIMENTAL DETAILS

The experiments were performed at the JUSIFA beamline at HASYLAB/Hamburg (FRG). The setup for the ASAXS measurements, described in detail in Ref. 3, was modified slightly for the magnetic measurements. In order to illuminate the sample with circular polarized x rays, the inclined view method was used. The beam position control monitor was set to an asymmetric position 2.5 mm above/below the orbital plane with a slit height of 1.4 mm. The beam height position was checked by recording the beam profile after each scan. The calculated degree of circular polarization amounts to $\approx 70\%$. A small solenoid provided

magnetic flux densities up to 60 mT with its field direction pointing parallel/antiparallel to the photon beam direction sufficient to saturate the sample.

The magnetic contrast scattering curve was then obtained according to Eq. (5) by recording two scattering profiles with parallel/antiparallel orientation of the magnetization relative to \hat{e}_z and fixed circular degree of polarization at an incident photon energy where the maximum dichroic effect is expected. The results reported here were obtained with a binary Gd₂₈Fe₇₂ system. The amorphous film was prepared by coevaporation from two electron-gun sources in a high vacuum system onto a 15 μm Mylar^R foil. For chemical protection, the Gd-Fe films of thickness $h = 105\text{--}115$ nm were covered with 20–22 nm Al layers on both sides of the Gd-Fe layer. A stack of 12 foils was enough to achieve a transmission of 0.5. A strong magnetic anisotropy perpendicular to the surface was verified by vibrating sample magnetometer (VSM) measurements and Faraday effect results

exhibiting a rectangular hysteresis loop with a magnetic coercive field of ≈ 20 mT.

III. RESULTS AND DISCUSSIONS

In Fig. 1 the magnetic scattering curve intensity obtained in that way versus momentum transfer Q measured at the Gd L_3 edge ($E=7243$ eV) is presented in comparison with the ASAXS profile obtained at the corresponding Fe K edge indicating the gross similarity of the electronic and magnetic structure. The profile can be interpreted as due to two size distributions, where the Q^{-4} behavior at small Q values can be attributed to large particles. After a pronounced maximum at $Q \sim 0.06 \text{ \AA}^{-1}$, which can be interpreted as a correlation maximum, the tail of a size distribution of smaller particles can be observed.

Fit procedures taking into account a log-normal distribution to the experimental data including a correlation yielded a correlation length of 74.9 \AA and size of the particle radius of 5.3 \AA with slightly enhanced values for the magnetic case (76.6 \AA and 5.8 \AA , respectively). The results are shown in Fig. 2, where the Q^{-4} tail of the large particles had been subtracted. Corresponding EXAFS and MEXAFS studies indicate no wide range ordering compared to pure bcc Fe.⁴ This points to a rather complex structure of the system studied. Although the crystal structure seems to be amorphous, there is to some extent an ordered chemical structure, which is consistent with the assumption that column-like structures are formed in that magneto-optical films. Furthermore, the observed magnetic anisotropy could also be related to those columns. On the other hand, the magnetic correlation observed in the MASAXS would then originate from a chemical inhomogeneity.

The intensity of the MASAXS profile can be related to accurate experimental measurements of MEXAFS in a wide range around the Gd L_3 edge with the help of the optical theorem [Eq. (2)] and a Kramers–Kronig relation. The obtained results in a pure Gd system for f' , f'_c and f'' , f''_c , respectively, as function of energy are shown in Fig. 3. From these data the contrast ratio between ASAXS and MASAXS observed in Fig. 1 can be directly deduced. It is interesting that this ratio is larger than the dichroic effect at $E = 7243$ eV observed in absorption due to the large contribu-

FIG. 5. MASAXS obtained at the Gd L_3 edge above (◇) and below (●) the orbital plane indicating the change of sign of the profile with circular degree of polarization.

tion of f'_c . However, similar enhanced effects have also been observed in magnetic resonant scattering in Ni.⁵

Characteristic features of X-MCD can be manifested by performing the MASAXS at the corresponding spin-orbit split L_2 edge of Gd. Taking into account the different values for $\langle \sigma_z \rangle$ at the $L_{3,2}$ edges their should be a change in sign of the scattering profile comparing the results at the $L_{3,2}$ edges. The MASAXS profiles shown in Fig. 4 exactly follow this feature as the direction of magnetization (N and S) has to be reversed (S–N) at the L_2 edge in order to yield the same sign of the profile compared to the L_3 edge (N–S) and the scattering intensity at the L_2 edge is decreased compared to the L_3 edge as expected. As the dichroic signal depends on the relative orientation of the circular polarization photons and the magnetization of the sample MASAXS spectra taken with reversed photon helicity, i.e., above and below the orbital plane (see Fig. 5) proof again a change of sign as expected.

IV. OUTLOOK AND CONCLUSION

Magnetic small angle x-ray scattering is a new technique, which allows valuable insights into structural characteristics of magnetic particles in granular systems and diluted alloys on a nm scale. Additional support to establish reliable models of the magnetic structures will be provided by magnetic imaging techniques allowing a quantitative information on the local magnetization with high resolution.⁶

A systematic study of x-ray magnetic circular dichroism, x-ray resonant magnetic scattering, and resonant inelastic x-ray scattering at the $L_{2,3}$ edges of Nd on $\text{Nd}_2\text{Fe}_{14}\text{B}$ is presented. The combined information allows to assign a dipolar or quadrupolar origin to different features appearing in the experimental spectra and to study the thermal dependence of the Nd moment orientation below the spin reorientation transition which takes place at $T_{\text{SRT}}=135$ K. © 1998 American Institute of Physics. [S0021-8979(98)25011-0]

The possibility offered by near-edge x-ray magnetic techniques of separately probing a given element in a material containing several magnetic species can be used to disentangle a wide set of problems on the magnetism of materials, as, for example, rare-earth (R)-transition metal (TM) intermetallics. However, the interpretation of x-ray magnetic circular dichroism (XMCD) and resonant magnetic scattering (XRMS) at the $L_{2,3}$ edges of R ions ($2p \rightarrow 5d$ transitions) has been a controversial subject since the first experimental results were obtained. It has been pointed out that, to properly describe the observed signals, several aspects had to be included in the analysis, among others the contribution from $2p \rightarrow 4f$ quadrupolar excitation channels in the pre-edge region.¹ In this article, we report on a combined study of XMCD, XRMS, and resonant inelastic x-ray scattering (RIXS) which allows to assign a multipolar origin to the different features appearing in the experimental spectra at the Nd $L_{2,3}$ edges, and to apply this information to the study of the thermal dependence of the orientation of the Nd magnetic moments upon the spin reorientation transition (SRT) taking place on $\text{Nd}_2\text{Fe}_{14}\text{B}$. Below $T_{\text{SRT}} \approx 135$ K, the easy axis magnetization direction (EMD) continuously rotates from the [001] axes (high- T phase) towards the [110] axis. Although the behavior of the bulk magnetization has been well determined, the evolution of the magnetic moments on the microscopic scale is less understood. It has been proposed that the Nd and Fe moments can be considerably noncollinear in the low-temperature phase.^{2,3} Different macro- and microscopic techniques have been applied to study the SRT, but no general agreement on the mutual orientation of the R and Fe moments in the low temperature phase has been reached so far.⁴

To directly study the reorientation angles of Nd atoms on the SRT, we measured temperature-dependent XMCD at the $L_{2,3}$ edges of Nd in a single crystal of $\text{Nd}_2\text{Fe}_{14}\text{B}$. The chosen geometry was as follows: the incident photon wave vector, \mathbf{k}_i , the [001] and the [110] axes of the plate-shaped single crystal lied in the horizontal plane, both [001] and [110] axes forming an angle of 45° with \mathbf{k}_i . A magnetic field of 1 T was applied parallel to \mathbf{k}_i . In the dipolar approximation ($2p \rightarrow 5d$ transitions), XMCD is proportional to $\cos(\alpha)$, where α is the angle between the Nd atomic magnetic moment, $\bar{\mu}_{\text{Nd}}$, and \mathbf{k}_i . Below T_{SRT} , $\bar{\mu}_{\text{Nd}}$ rotates from the [001] axes by an angle $\theta_{\text{Nd}}(T)$. Consequently, the described XMCD experiment is sensible to both, $\theta_{\text{Nd}}(T)$ (through $\alpha(T) = 45^\circ - \theta_{\text{Nd}}(T)$) and $\mu_{\text{Nd}}(T)$.

Figure 1 shows five representative XMCD spectra at the $L_{2,3}$ edges of Nd in $\text{Nd}_2\text{Fe}_{14}\text{B}$ recorded at different temperatures in the vicinity of SRT, as indicated in the figure. Two

main features (labeled “a1” and “b”) are observed in the edge and pre-edge region, while a smaller shoulder (labeled “a2”) is only observed at the L_3 edge. 170 and 150 K XMCD curves are very similar at both edges, indicating the magnetic saturation of the sample in this range of temperature, above T_{SRT} and well below $T_c \approx 600$ K. The XMCD spectra recorded at 150, 130, and 110 K present a noticeable enhancement coincident with T_{SRT} . Below 110 K, XMCD remains again almost independent of temperature, showing no differences between 110 and 50 K. These experimental results reflect the sensibility of the technique to the SRT occurring below 135 K. However, the interpretation of the observed thermal variations is not simple: the spectra recorded at different temperatures do not scale, as it should be the case if the whole signal would have a single dipolar (E1) origin and the only differences would be originated by $\theta_{\text{Nd}}(T)$. This is more evident at the L_2 edge, where the a1 feature is only observed below T_{SRT} . It has been theoretically pointed out^{1,5} and experimentally confirmed⁶ that the pre-edge features in $L_{2,3}$ dichroic spectra in rare earth ions have its origin in quadrupolar (E2) $2p \rightarrow 4f$ transitions.

XRMS is the scattering counterpart of XMCD.⁷ It allows to discriminate the multipolar origin of the observed magnetic signals by studying different Bragg reflections, as dipolar and quadrupolar contributions have different angular dependence. We performed room-temperature XRMS on $\text{Nd}_2\text{Fe}_{14}\text{B}$ on several ($hh0$) reflections at the $L_{2,3}$ edges of Nd. ($hh0$) Bragg reflections were selected because the two nonequivalent crystallographic sites occupied by Nd ions, 4f and 4g, contribute very differently to the structure factor for different h values. This fact, although it is not the objective of the present study, allow to deconvolute the resonant magnetic signal created by Nd ions occupying 4f and 4g sites.

The experimental results are shown in Fig. 2. Their spectral shape reflects roughly that of XMCD and, within the experimental errors, the same features are present at both edges (a1 feature is visible even at room temperature in (220) and (330) reflections at the L_2 edge). Full lines in Fig. 2 are the results of a fitting procedure based on the standard interpretation of XRMS⁷ by means of a regularization technique analysis. A proper fitting of the whole data set was only

FIG. 3. RIXS intensity at four incident energies (left panel) and CFS scans (right panel, thin lines) together with XMCD (thick line) at Nd L_3 edge on $\text{Nd}_2\text{Fe}_{14}\text{B}$. RIXS data are scaled as indicated in both panels.

possible by allowing for a E2 origin for a1 and a2 features, with an intensity which at the L_3 edge is comparable to that of the E1 one (b and higher energy features).

Standard absorption measurements at the $L_{2,3}$ edges of rare-earth ions cannot separate the two E1 and E2 excitation channels due to the $2p$ core-hole lifetime broadening. However, it has been shown that such a separation can be achieved by means of resonant inelastic x-ray scattering (RIXS) experiments.⁸ In Nd, this can be realized by studying the resonance behavior of the $4d^9 4f^4 5d^0$ and the $4d^9 4f^3 5d^1$ final state multiplets as the incident photon energy is tuned through the $2p^5 4f^4 5d^0$ and $2p^5 4f^3 5d^1$ intermediate state excitation energies, monitoring the $4d_{5/2,3/2} \rightarrow 2p_{3/2}$ radiative decay channel $L\beta_{2,15}$ of Nd. In Fig. 3 (left panel), we present as a function of the energy transfer, ΔE , four representative RIXS spectra obtained at different fixed incident energies, E_i , (indicated in the figure) in the vicinity of the Nd L_3 edge. The spectrum recorded at $E_i = 6210$ eV $\approx E_{L_3}$ corresponds to the largest incident energy at which the maximum of the central feature, labeled “B,” remains at $\Delta E \approx 121.6$ eV, indicating that the photoelectron has been excited to a $5d$ localized intermediate state without acquiring extra kinetic energy. At higher incident energies (upper curve), this feature moves towards higher ΔE as the photoelectron acquires extra kinetic energy when promoted to the $5d$ band. The two lower spectra were recorded with E_i in the pre-edge region. Two extra channels, labeled “A1” and “A2” appear as distinct shoulders in the RIXS spectra at $\Delta E \approx 115.5$ and 118.5 eV. Previous experimental results⁸ and theoretical calculations⁹ allow an unambiguous assignment of features A1, A2, and B. Feature B is assigned to the $4d^9 4f^3 5d^1$ final state multiplet, resonantly enhanced at the $2p^5 4f^3 5d^1$ intermediate state excitation energies, corresponding to the strong dipolar $2p \rightarrow 5d$ channel. Features A1 and A2 are ascribed to the $4d^9 4f^4 5d^0$ final state multiplets which are resonantly enhanced at the $2p^5 4f^4 5d^0$ intermediate state excitation energies, corresponding to the weak quadrupolar $2p \rightarrow 4f$ excitation channel. Features A1 and A2 are observed at lower ΔE values than feature B, i.e., at smaller intermediate state excitation energies. This is consistent with the strength of the Coulomb interaction between the pro-

moted electron and the $4d$ core hole resulting in a $4d^9 4f^4 5d^0$ final state more strongly bound than the $4d^9 4f^3 5d^1$ or $4d^9 4f^3 5d^1 \epsilon^*$ states.

To directly compare the inelastic scattering spectra with the XMCD, the evolution of the peak intensities of features A1, A2, and B is monitored by scanning the incident and scattered photon energy together, thus keeping ΔE constant and fixed to the values corresponding to the excitation energies of features A1, A2, and B, respectively. These constant-final-state (CFS) spectra are reported in Fig. 3 (right panel, thin line) together with the corresponding L_3 edge XMCD (thick line) measured on the same sample.

It is evident that features A1, A2, and B correspond to three different resonances, reaching their maximum intensity at different incident photon energies and that their correspondence with the XMCD features below and at the edge is rather evident. The energy position around which the dipolar B resonance is centered corresponds to the strongest feature in the XMCD spectra. This observation is in agreement with the commonly accepted interpretation of the XMCD signal at the absorption threshold. More importantly, A1 and A2 features resonate at two different energies, in coincidence with the a1-a2 structure in the Nd L_3 XMCD.

Once the origin of a1, a2, and b features of the XMCD spectra at the L_3 edge has been determined, we can properly treat the temperature variation of the dichroic signals, obtaining information about $\theta_{\text{Nd}}(T)$. Although the strong differences in the relative E2/E1 intensity between the two absorption edges remain to be fully explained, there have been theoretical efforts¹⁰ which qualitatively describe the observation, predicting an up-to-now never observed quadrupolar contribution to the XMCD at the L_2 edge of rare-earth ions. It is well known¹¹ that the intensity of a dichroic E1 contribution depends linearly on $(W_{1,1} - W_{1,-1})\cos\alpha$, while a E2 one is proportional to $((W_{2,1} - W_{2,-1})\cos 2\alpha + (W_{2,2} - W_{2,-2})\sin^2\alpha)\cos\alpha$, where $W_{L,M}$ are the matrix elements the 2^L pole transitions. Given the order of magnitude of the involved transition energies, $W_{L,M}$ will be treated as temperature independent in the range of interest of our study. By integration of the dichroic intensities, the $W_{L,M}$'s remain in the equations as constant factors. We have studied the temperature dependence of the E2/E1 intensity ratio at both edges. The temperature dependence of XMCD through $\mu_{\text{Nd}}(T)$ is overcome by studying the ratio between two dichroic signals which depend on the same way on $\mu_{\text{Nd}}(T)$. The experimental ratio values obtained at both edges are shown in Fig. 4. Furthermore, we have fitted the temperature dependence of the E2/E1 ratio to the theoretical angular dependence calculated by using the $\theta_{\text{SR}}^{\text{Nd}}(T)$ values corresponding to the strongly noncollinear arrangement in the low-temperature phase conjectured by Onoedera² from ^{57}Fe Mössbauer spectroscopy data. The remarkable agreement of the fit to the experimental E2/E1 ratio strongly supports Onoedera's prediction, with an average value of $\theta_{\text{Nd}} \approx 57^\circ$ to

FIG. 4. Temperature dependence of the E2/E1 ratio of the XMCD spectra at the L_2 (open symbols) and L_3 (crossed squares) absorption edges. The thick line corresponds to the expected behaviour for the predicted noncollinear configuration between Fe and Nd ions in Ref. 2 for a dipolar b and quadrupolar a1 and a2 features.

compare with $\theta_{\text{Fe}} \approx 27^\circ$ at the lowest temperatures. The observed angular behavior of E2/E1 at the L_2 edge (coincident with that from L_3) is, to the authors knowledge, the first experimental evidence of a quadrupolar contribution to the dichroism of a rare-earth ion at the L_2 edge.

In summary, our combined XMCD, XRMS, and RIXS study at the Nd $L_{2,3}$ edges in the $\text{Nd}_2\text{Fe}_{14}\text{B}$ has allowed to separately observe the E1 and E2 absorption channels, evidencing the E2 origin of the magnetic pre-edge features at both edges in XMCD and XRMS and showing how this different spectroscopic origin provides new information on the magnetic properties of materials.

This work has been partly financed by Spanish CICYT, project MAT96/448. XMCD and XRMS experiments were performed at ID12A and BM32 beamlines at the ESRF, respectively. RIXS experiments were performed at X21 at NSLS. The authors highly acknowledge the staff of both facilities for the kind support received.

Epitaxial $\text{Fe}_{100-x}\text{Co}_x/\text{Ag}(001)$ alloy films: Structure and element-specific magnetic moments from magnetic linear dichroism

E. Kisker, A. Faust, R. Schellenberg, A. Fanelisa, and F. U. Hillebrecht
Heinrich-Heine-Universität Düsseldorf, Universitätsstrasse 1, 40225 Düsseldorf, Germany

The structure and element-specific local magnetic moments in $\text{Fe}_{100-x}\text{Co}_x/\text{Ag}(001)$ ($16 < x < 70$) epitaxial ultrathin alloy films have been determined by photoelectron diffraction (PED) and related magnetic linear dichroism in angle-resolved core-level photoemission, using a laboratory x-ray source. The PED peaks of the Fe and Co $2p$ core levels for any of the alloy compositions are at emission angles as expected for a bcc lattice. The dichroism increases for the Fe $2p_{3/2}$ core level with increasing x , whereas that of the Co $2p_{3/2}$ dichroism is virtually independent on the alloy composition. The dichroism of both the Fe and the Co core levels scales well with the calculated dependence of the local magnetic moment on the alloy composition rather than with the average saturation magnetization. © 1998 American Institute of Physics. [S0021-8979(98)40311-6]

I. INTRODUCTION

We have shown recently that the photoemission intensity in angle-resolved core level photoemission with linearly (p)-polarized radiation depends on the direction of the magnetization.¹ Subsequently it was shown² that this effect persists when using unpolarized radiation from standard laboratory x-ray sources (e.g., Mg or Al K_α), due to the presence of the p -polarized component. Consequently, this experimentally relatively easily accessible effect can be used for element-specific magnetometry. Within a purely atomic picture, the dichroism at a fixed energy is proportional to $M \cdot (k \times E) \cdot (k \cdot E)$.³ In dealing with a crystalline solid, the emission angle α of the photoelectrons with respect to the crystal lattice is an additional variable. Changing α gives rise to well-known photoelectron diffraction patterns, characterized by dominant forward scattering peaks along low-index crystallographic directions at photoelectron energies exceeding about 400 eV. The emission angle dependence of the dichroism is strongly affected by photoelectron diffraction, the latter being an independent source for an intensity asymmetry upon a change in magnetization direction.^{4,5} Accordingly, information on the geometric structure and on magnetic properties is obtained from the dichroism data. Here we will apply this method for the first time to element-specifically determine the magnetic moment in epitaxial $\text{Fe}_{100-x}\text{Co}_x$ alloy thin films.

II. EXPERIMENT

Figure 1 shows the experimental geometry. We used a standard x-ray photoelectron spectrometer (CLASS 150, VSW) and a Mg K_α x-ray source. The spectrometer and the x-ray source make an angle of 45° with respect to each other, the electron emission direction is in the incidence plane. The emission angle (α) of the photoelectrons with respect to the crystal lattice is varied by rotating the sample around an axis perpendicular to the plane of incidence. The sample surface was a (100) plane of the bcc lattice, which prevailed for all alloy concentrations, and the axis of rotation coincided with a (100) direction in the plane of the surface. Consequently,

the scanned emission directions were also in a (100) plane. The samples are remanently magnetized by a short field pulse of about 80 Oe prior to performing an energy scan at a preset value of α . The geometrical conditions between \mathbf{M} , \mathbf{k} , and \mathbf{E} remain constant when α is changed. A wide range in α was spanned to obtain the PED and the intensity asymmetry pattern. The films, obtained by coevaporation of Fe and Co onto an Ag(001) substrate at room temperature from e -beam heated rods, were 20 ML thick.

III. DATA EVALUATION

The dichroism is quantified by its asymmetry value, $A = (I^\uparrow - I^\downarrow)/(I^\uparrow + I^\downarrow)$, where I^\uparrow, \downarrow are the intensities for the two magnetization directions. When the alloy composition is changed, the line-to-background ratio changes. Since we are concerned with determining the intensity asymmetry of core level lines from different alloy compositions, background subtraction is mandatory. Here we subtract constant backgrounds as determined by the intensities at the onset of the $2p_{3/2}$ core level spectra prior to calculating the dichroism. In

FIG. 1. The experimental geometry. The unmonochromatized Mg K_α radiation and the acceptance cone of the photoelectron spectrometer are at an angle of 45° . The sample is rotated about its [100] direction to vary the angle (α) between the surface normal (\mathbf{n}) and the photoelectron collection direction.

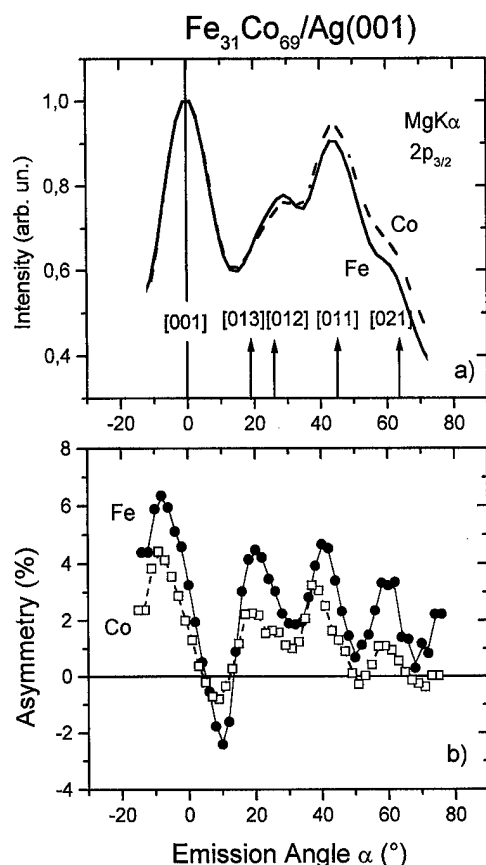

FIG. 2. Angular dependences of the photoelectron intensities (a) and asymmetries (b) as obtained from the $2p_{3/2}$ core levels of an epitaxial $\text{Fe}_{31}\text{Co}_{69}/\text{Ag}(001)$ alloy film. Full line and filled circles are for Fe, dashed line and empty squares for Co. Vertical bars indicate the emission angles corresponding to low-index crystallographic directions.

plots showing angular dependences the asymmetry is plotted. Since the asymmetry tends to diverge where the background subtracted intensity becomes very small, we plot the intensity difference normalized to the maximum in $(I^\uparrow + I^\downarrow)$ in plots showing binding energy dependences. This so-called normalized intensity difference is equal to the asymmetry at that binding energy where $(I^\uparrow + I^\downarrow)$ has its maximum value.

The intensity asymmetry caused by PED is large and easy to measure in a conventional XPS spectrometer. However, extracting the full amount of information on the structural and magnetic properties requires one to fit the dichroism data by a PED theory since no simple quantitative interpretation of the angular dependence of the intensity asymmetry on structural and magnetic properties has been given so far. We therefore chose to average out the PED oscillations in the dichroism data by integrating over the emission angle. Since the dichroism oscillations are not symmetric with respect to zero dichroism, the angular averaged asymmetry curve is different from zero. We have shown recently that such angular integrated data obtained from $\text{Fe}(001)$ compare well with data from an amorphous Fe containing metallic glass where PED effects are absent.⁵ The PED intensity diffraction pattern still provides the opportunity to simultaneously get information on the crystal structure.

FIG. 3. Dependence of the linear magnetic dichroism, obtained with unpolarized light, on alloy composition (left scale) for Fe (circles) and Co (squares). The curves show results calculated by Turek *et al.* (Ref. 6, right scale) for the local moments of Fe (upper) and Co (lower), as well as the concentration-weighted average (dashed).

IV. RESULTS

Energy distribution curves have been measured for the Fe and Co $2p_{3/2}$ and $2p_{1/2}$ core levels for emission angles ranging from -20° to 70° . For any of the alloy compositions studied, we observe well-defined photoelectron diffraction peaks for each of the Fe $2p_{3/2}$, Fe $2p_{1/2}$, Co $2p_{3/2}$, and Co $2p_{1/2}$ peaks. Because of their higher intensities, the $j=3/2$ sublevels are evaluated here. Figure 2(a) shows the angular distributions of the photoelectron intensities for the peak energies of the Fe and Co $2p_{3/2}$ photoemission lines, and Fig. 2(b) shows the angular distribution of the associated intensity asymmetries for an epitaxial $\text{Fe}_{31}\text{Co}_{69}/\text{Ag}(001)$ alloy film. Well-defined peaks in the intensity are observed at emission angles corresponding to the $\langle 001 \rangle$ (0°), $\langle 012 \rangle$ (18.4°), $\langle 013 \rangle$ (26.6°), $\langle 011 \rangle$ (45°), and $\langle 021 \rangle$ (63.4°) forward-scattering directions. The peaks corresponding to the $\langle 013 \rangle$ and $\langle 012 \rangle$ directions merge into one broader peak. The asymmetry changes sign in going from $\alpha = -10^\circ$ towards $\alpha = +10^\circ$ and oscillates further with increasing angle. The pattern can be viewed as a virtually symmetrical oscillation offset from zero by about 2%. The oscillations at larger angles are reduced in amplitude from that centered at normal emission ($\alpha = 0$). The angular dependences are virtually independent on the alloy composition and compare well with those observed in pure $\text{Fe}/\text{Ag}(001)$ films.

The concentration dependence of the element-specific dichroism is shown in Fig. 3. When changing the alloy composition from 16% to about 70% Co concentration, a slight increase of the dichroism is observed for the Fe $2p_{3/2}$ core level, whereas the dichroism of the Co $2p_{3/2}$ is essentially independent on the composition. These findings compare

well with the calculated dependence of the magnetic moments for bulk random bcc $\text{Fe}_{100-x}\text{Co}_x$ alloys.^{6,7} It is worthwhile to mention that the Fe and the Co dichroism as a function of the Co concentration does not follow the dependency of the average moment which decreases by 20% in going from $x=16$ to $x=70$ as a result of the smaller magnetic moment of the Co as compared to that of the Fe. This shows that the magnetic linear dichroism probes the element-specific local magnetic moments.

V. CONCLUSIONS

We have shown that structural and magnetic properties of a composite material can be determined by photoelectron diffraction and the related magnetic linear dichroism in angle-resolved core level photoemission, using an unpolarized laboratory x-ray source. The dependence of the element-specific $2p_{3/2}$ core level dichroism of Fe and Co in epitaxial $\text{Fe}_{100-x}\text{Co}_x/\text{Ag}(001)$ alloy films compares well the calculated dependences of the local magnetic moments on the alloy composition.

We present the magnetocrystalline anisotropy of disordered $\text{Ni}_{1-x}\text{Pt}_x$ and disordered fcc $\text{Co}_{1-x}\text{Pt}_x$ alloys using the spin-polarized relativistic Korringa–Kohn–Rostoker coherent-potential approximation in which the spin-orbit coupling and magnetism are treated on an equal footing. In both the pure fcc ferromagnetic elements (Ni as well as Co), the magnetic easy axis is along the [111] direction of the crystal. Addition of Pt to Ni changes the magnetic easy axis to the [001] direction, in agreement with the experimental observations, although the magnitudes of the calculated magnetocrystalline anisotropy energies for different compositions are somewhat different from the corresponding experimental values. In contrast, addition of Pt to Co does not alter the magnetic easy axis, only the magnitude of the magnetocrystalline anisotropy energy is affected. The origin of this contrasting behavior may lie in the larger size of the magnetic moment of Co (as compared to Ni). © 1998 American Institute of Physics. [S0021-8979(98)33911-0]

Magnetocrystalline anisotropy of a ferromagnetic material is a consequence of the coupling of the spin of the electron with its orbital motion. This so-called spin-orbit coupling (SOC), though very small compared to the exchange energy responsible for the magnetism, determines the equilibrium or “easy” axis of magnetisation in most solids. Clearly, SOC is a relativistic phenomenon and can only be adequately described in a fully relativistic formalism in which magnetism and SOC are treated on an equal footing. In a recent publication,¹ we presented a scheme to calculate the magnetocrystalline anisotropy energy (MAE) of a disordered alloy within the spin-polarized relativistic Korringa–Kohn–Rostoker coherent-potential approximation (SPR-KKR-CPA).² This theory is based on the relativistic spin-polarized density functional theory derived by MacDonald and Vosko³ and others. Within this formalism, the MAE of a system is expressed as

$$\begin{aligned} \Delta E = & -\frac{1}{\pi} \text{Im} \int^{E_F} d\epsilon \left[\frac{1}{\Omega_{BZ}} \int d\mathbf{k} \ln \|I + [t_c^{-1}(\mathbf{e}_2) \right. \\ & - t_c^{-1}(\mathbf{e}_1)] \tau_c(\mathbf{k}; \mathbf{e}_1) \| + x \{ \ln \|D_A(\mathbf{e}_1)\| \\ & - \ln \|D_A(\mathbf{e}_2)\| \} + (1-x) \{ \ln \|D_B(\mathbf{e}_1)\| \\ & - \ln \|D_B(\mathbf{e}_2)\| \} \Big] - \frac{1}{2} n(E_{F_2}; \mathbf{e}_2) (E_{F_1} - E_{F_2})^2 \\ & + \mathcal{O}(E_{F_1} - E_{F_2})^3. \end{aligned} \quad (1)$$

In Eq. (1), $t_c(\mathbf{e}_1)$ and $t_c(\mathbf{e}_2)$ are the SPR-KKR-CPA t -matrices for magnetization along \mathbf{e}_1 and \mathbf{e}_2 directions, respectively, and $\tau_c(\mathbf{k}; \mathbf{e}_1)$ is the path-operator matrix in the \mathbf{k} -space,

$$\tau_c(\mathbf{k}; \mathbf{e}_1) = [t_c^{-1}(\mathbf{e}_1) - g(\mathbf{k})]^{-1} \quad (2)$$

and

$$D_A(\mathbf{e}_1) = [I - \tau_c^{00}(\mathbf{e}_1) \{t_c^{-1}(\mathbf{e}_1) - t_A^{-1}(\mathbf{e}_1)\}]^{-1} \quad (3)$$

with similar expressions for $D_A(\mathbf{e}_2)$, $D_B(\mathbf{e}_1)$, and $D_B(\mathbf{e}_2)$.

The striking feature of Eq. (1) is that the MAE can be calculated directly. This is in contrast with some other approaches which involve the subtraction of the total energies of the system for two magnetization directions calculated separately. Therefore, the use of Eq. (1) guarantees against many possible numerical instabilities.⁴ In particular, Eq. (1) is derived by algebraically canceling many terms in the total energy, e.g., all core contributions. Remember that the energy difference is only a tiny fraction ($\sim 10^{-10}$) of the total energy, and thus impossible to extract as the difference in the total energies except when the total energies are calculated with the utmost precision. The use of Eq. (1) also reduces the systematic error by ensuring that the same integration grids are used for both magnetization directions (this is not guaranteed when the two total energies are calculated separately). Additionally, in most cases, the second term of Eq. (1) is expected to be quite small compared to ΔE , and in such cases we need to know the Fermi energy corresponding to only one magnetization direction. The first term which contains the predominant contribution to ΔE needs to be evaluated accurately. The Brillouin zone integration involved in the above equation is the most time-consuming part of the calculation. Owing to the preferred direction of magnetization, the symmetry in the Brillouin zone is reduced and it is necessary to perform the Brillouin zone integration in the 1/16 of the zone when the magnetization is along the [001] direction and in the 1/4 of the zone when it is along the [111] direction (as opposed to 1/48 in the nonrelativistic case) for cubic systems. Also, if the k -points are not sampled properly, it may take as many as 500 000 k -points to get a converged result as has been demonstrated in earlier studies.⁵

FIG. 1. Magnetocrystalline anisotropy energy (MAE) defined as $E(001) - E(111)$ for $\text{Co}_{1-x}\text{Pt}_x$ alloys as a function of Pt concentration. The solid line is a guide to the eye.

Our method and its computational aspects have been discussed in detail elsewhere.¹ In what follows, we briefly describe the important points relevant to the present study. We start with the self-consistent potentials obtained by the spin-polarized scalar relativistic KKR-CPA. The SPR-KKR-CPA equations are solved for two magnetization directions separately to a high degree of precision (10^{-9}). The energy integration is performed around a complex contour in order to obtain an accurate integration with comparably fewer points.⁶ The Brillouin zone integration is performed by the recently proposed hybrid adaptive quadrature scheme.⁷ In our earlier study¹ we had used the prism method⁸ and we needed $\sim 100\,000$ k -points to achieve a good convergence in MAE. The advantage of the hybrid method is that it puts more points only where needed and therefore the number of k -points is greatly reduced. In our calculations we have found that, when the energy is near the real axis, we have to put $\sim 25\,000$ points for a good convergence whereas far from the real axis we need much less number of k -points (For example, when the imaginary part of the energy is 0.5 Ry, we need only 100 points to achieve same level of convergence.)

In this article, we present the MAE of disordered fcc $\text{Co}_{1-x}\text{Pt}_x$ and $\text{Ni}_{1-x}\text{Pt}_x$ alloys. We note that in both fcc Co as well as fcc Ni the easy magnetic axis is along the [111] direction of the crystal and the theoretical calculations also predict the same.¹ In Fig. 1 we show the results of our calculations for these alloys. We note that the MAE for $\text{Co}_{1-x}\text{Pt}_x$ alloys, defined as $E(001) - E(111)$ remains positive throughout the whole concentration range implying that the magnetic easy axis remains unchanged at [111]. The MAE is maximum around the equiatomic composition. To our knowledge there are no experimental results on the bulk disordered fcc $\text{Co}_{1-x}\text{Pt}_x$ alloys. However, the experimental results for the ordered Co-Pt alloy are very different from our calculated results for disordered alloys; both the magnitude of the MAE as well as the magnetic easy axis are different ($\text{MAE} \sim 400 \mu\text{eV}$). The reason for this could lie in either the compositional ordering or in the tetragonal distortion or in a combination of the two. We are working on this aspect and we defer it to a later publication.

Experimental results on ferromagnetic $\text{Ni}_{1-x}\text{Pt}_x$ alloys (which are disordered and fcc) reveal that the easy axis of magnetisation changes to [001] with the addition of Pt with

FIG. 2. Experimental and theoretical values of magnetocrystalline anisotropy energy (MAE) defined as $E(001) - E(111)$ for $\text{Ni}_{1-x}\text{Pt}_x$ alloys as a function of Pt concentration. The lines are guide to the eye.

the magnitude of MAE being largest around 15% Pt.⁹ In Fig. 2 we show our calculations and the experimental results; both show similar trends, although the magnitudes of MAE differ. Also, the minima around 15% Pt is less pronounced than that in the experimental results. Nevertheless, we reproduce the experimental observations that addition of Pt to Ni alters the easy magnetic axis. Further calculations and measurements are needed to examine the extent of the agreement. However, it is important to realize that, although both fcc Ni and fcc Co have their magnetization vectors pointing along the [111] direction, addition of Pt to Ni changes the magnetic easy axis. Whereas when Pt is added to Co, the easy axis is not affected; only the magnitude of the MAE is changed. Both the size of the magnetic moment as well as the SOC are important factors that determine the magnetocrystalline anisotropy of a material. In the present alloy systems, the SOC are similar in strength. Thus, it seems possible that this contrasting behavior originates in the size of the magnetic moment. The larger moment of cobalt (compared to nickel) seems to stabilize the direction of the easy axis, although other mechanisms are also possible, e.g., sensitivity to the position of the Fermi level.⁵

In summary, we have presented calculations of MAE of $\text{Co}_{1-x}\text{Pt}_x$ and $\text{Ni}_{1-x}\text{Pt}_x$ alloys within the SPR-KKR-CPA scheme. Our results show that, besides the known SOC effect, the size of the magnetic moment also plays a role in determining the magnetocrystalline anisotropy of a material. We end by pointing out the need of a more comprehensive approach to the calculation of the magnetocrystalline anisotropy energy which should include the effects of atomic short-range order and loss of cubic symmetry.

The electronic structure and the magnetism of a $\text{Mn}_{12}\text{O}_{12}$ molecule at ground state have been studied by density functional theory with a local spin density approximation. We have found that the magnetic moments of Mn ions in the tetrahedron and those of Mn ions in the crown of the $\text{Mn}_{12}\text{O}_{12}$ molecule align antiferromagnetically. The average moment per Mn ion is about $3.07\mu_B$ in the tetrahedron and $4.07\mu_B$ in the crown. The total spin amounts to $20.0\mu_B$ which is in agreement with recent experimental results. The significant difference of magnetic moments between Mn ions at two sites is attributed to the different exchange splitting of $3d$ orbitals. However, the charge difference between the two kinds of Mn ions is as small as 0.22 electrons. The charge density and the spin density exhibit strong directional dependence, which indicates the strong anisotropy in this molecule. © 1998 American Institute of Physics. [S0021-8979(98)40411-0]

The study of large molecular clusters of metal ions is a very important area of interest which is expanding rapidly.¹ Very recently, many new phenomena such as the quantum tunneling of magnetization, gigantic relaxation time and magnetic bistability²⁻⁸ were discovered in a so-called high-spin molecular organic compound— $\text{Mn}_{12}\text{O}_{12}$ acetate.^{9,10} These new observations have further enhanced the interest because of its suitability for the investigation of magnetic properties on nanoscale or mesoscopic dimensions, and its promise of use in data storage devices.

$\text{Mn}_{12}\text{O}_{12}$ acetate has a well-defined crystal structure which can be described as a $\text{Mn}_{12}\text{O}_{12}$ molecule surrounded by some organic ligands.^{9,10} The molecule contains two kinds of manganese ions bridged by oxygen. The inner four ions form a tetrahedron in the center of cluster (denoted by Mn_t) and the outer eight form a crown (denoted by Mn_c). A recent experiment¹¹ shows that the molecule has a large net spin $S=10$, which is always oriented along the easy axis S_4 . Although a strong interplay could exist in the $\text{Mn}_{12}\text{O}_{12}$ molecule, the interaction between the molecules themselves is still weak because of the large distance. Many experiments^{2-8,10} have shown that at low temperature, the $\text{Mn}_{12}\text{O}_{12}$ molecule acts just like a high-spin magnet with clean discrete quantum numbers ($m_s = -10, \dots, +10$). So, unlike many other nanomagnetic materials, the magnetic behavior of $\text{Mn}_{12}\text{O}_{12}$ acetate should be mainly determined by the $\text{Mn}_{12}\text{O}_{12}$ molecule.

So far, in spite of some experimental observations²⁻¹³

having been made, there is still a lack of many theoretical studies^{14,15} for such an interesting material, especially studies of the electronic structure and the magnetism on a microscopic level. In this article, we report our results of first principle studies on the $\text{Mn}_{12}\text{O}_{12}$ molecule. We have employed the discrete variational method (DVM)^{16,17} based on density functional theory (DFT) with a local spin density approximation (LSDA)¹⁸ to study the ground state properties of the $\text{Mn}_{12}\text{O}_{12}$ molecule. In DVM, the Kohn-Sham equation (in atomic units),

$$(-\nabla^2/2 + V_C + V_{XC})\phi_{i\sigma} = \epsilon_{i\sigma}\phi_{i\sigma}, \quad (1)$$

with charge density $\rho_\sigma(\mathbf{r})$,

$$\rho_\sigma(\mathbf{r}) = \sum_i n_{i\sigma} |\phi_{i\sigma}(\mathbf{r})|^2 \quad (2)$$

is solved self-consistently where $\phi_{i\sigma}$ is the single particle wave function for the molecule with occupation $n_{i\sigma}$, V_C is the Coulomb potential of the nuclei and electrons, and V_{XC} is the exchange-correlation potential under LSDA. In the present calculation, the numerical atomic orbitals obtained by self-consistent LDA calculations for a single atom are used as the variational bases to expand the one particle wave functions. The discrete summation method of pseudo-random points in the three dimensional space and group theory are adopted to simplify the solution of the eigenvalue equations. The Coulomb potential is obtained by means of fitting charge density to a multipolar expansion which ensures that the DVM gives more precise results.¹⁷ In our calculation, the order of the multipolar expansion functions has

			Charge +2.60	Total -4.07

been chosen up to 2. The density of states (DOS) is obtained by using the Lorentzian broadening scheme, and the partial DOS (PDOS) is defined as:

$$D_{nl\sigma}^q = \sum_i P_{nl\sigma}^q \frac{\delta/\pi}{(\epsilon - \epsilon_{i\sigma})^2 + \delta^2}, \quad (3)$$

where $P_{nl\sigma}^q$ is the Mulliken population¹⁹ of the atomic orbital χ_{nl} of atom q in the molecular spin orbital $\phi_{i\sigma}$. The DOS of atom q with spin σ is obtained by a sum of n , l and i , and the total DOS of spin σ is given by the sum of all the atoms. To check the reliability of our method on the Mn-O system, we first study antiferromagnetically coupled MnO. We found magnetic moment of about $4.98\mu_B$ for the Mn cation, which is in agreement with experimental result.²⁰

For calculation of the $\text{Mn}_{12}\text{O}_{12}$ molecule, we adopted the experimental atomic distance,⁹ and put the z axis parallel to the easy axis. In Table I, we have presented magnetic moments, Mulliken orbital occupation numbers and charges for the Mn cations. From Table I, it can be seen the magnetic moment of the Mn_i cation is about $3.07\mu_B$ and that of the Mn_c cation is about $-4.07\mu_B$, which suggests that the two kinds of manganese ions are antiferromagnetically coupled. Considering the small contribution from the O anion, we get a total net spin amounting to $20.0\mu_B$ for the $\text{Mn}_{12}\text{O}_{12}$ molecule, which is exactly the same as the data derived from the experiment.¹¹ At the same time, we note that there is a large difference in Mulliken occupation numbers for the Mn 3d orbitals with spin up and with spin down. For the Mn_i cation, the electron occupation number in the 3d orbital with spin up is about 3.62, but it is only 0.55 in 3d orbital with spin down while, for the Mn_c cation, the electron occupation numbers of the 3d orbital with spin up and spin down are 0.14 and 4.22, respectively. In addition, for all the Mn ions, there are nearly no electrons in the 4s orbital, most of them have been transferred to oxygen atoms. The different occupation numbers show that the exchange splitting might have a significant difference for both kinds of Mn ions. In order to see this difference more clearly, we have presented the 3d PDOS of Mn cations as well as the total DOS of the $\text{Mn}_{12}\text{O}_{12}$ molecule in Fig. 1 and Fig. 2, respectively. From Fig. 1, the very large exchange splitting in the Mn 3d orbitals can be clearly observed, and both the spin-up and the spin-down PDOS have similar distribution. From PDOS, we can get the average value of the calculated exchange splitting, which is about 4.5

FIG. 1. The 3d PDOS for spin-up (upper panel) and spin down (lower panel) of the Mn_i cation (solid lines) and of the Mn_c cation (dashed lines). The Fermi level is shifted to zero.

eV for Mn_i cations and 3.0 eV for Mn_c cations. The large difference of exchange splitting between Mn_c and Mn_i ions leads to the large difference of magnetic moments, although the total occupation numbers in 3d orbitals are almost the same. From the total DOS shown in Fig. 2, the large net spin resulting from the large orbital exchange splitting in the $\text{Mn}_{12}\text{O}_{12}$ molecule can be observed. The charges for the two kinds of Mn ions are different, but their difference is small, only about 0.22.

To check the dependence of magnetic moment on the atomic distance, we have performed the calculations with the atomic distance 15% larger or smaller than the experimental result. We found that the total magnetic moment of the $\text{Mn}_{12}\text{O}_{12}$ molecule remains the same. For each Mn ion, the magnetic moment changes only a few percent. These results indicate that the magnetic properties of the $\text{Mn}_{12}\text{O}_{12}$ molecule are insensitive to the atomic distance.

In Fig. 3 and Fig. 4, we have presented the charge density as well as the corresponding spin density contour plots on the plane perpendicular to the S_4 axis (denoted by σ_h) and the plane including the S_4 axis and that perpendicular to

FIG. 2. The total DOS for spin up (upper panel) and spin down (lower panel) of the $\text{Mn}_{12}\text{O}_{12}$ molecule.

FIG. 3. Charge density (left panel) and spin density (right panel) contours of the $\text{Mn}_{12}\text{O}_{12}$ molecule on the plane perpendicular to the S_4 axis. The solid line stands for the positive value, and dashed line stands for the negative value.

σ_h (denoted by σ_v). On plane σ_h , it is obvious that, other than being spherical-like, the distribution of the charge density and the spin density for all Mn cations exhibits extremely strong directional dependence. However, on plane σ_v , the charge density and the spin density for Mn_c cations are spherically distributed, and those for Mn_t cations are only somewhat distorted from a spherical distribution. The strong directional dependence of the charge density and the spin density shows the large anisotropy of charge density and spin density in the $\text{Mn}_{12}\text{O}_{12}$ molecule which are mainly due to the distinction of neighboring atoms for Mn cations. So, it can

FIG. 4. Charge density (left panel) and spin density (right panel) contours of the $\text{Mn}_{12}\text{O}_{12}$ molecule on the plane including the S_4 axis. The solid line stands for the positive value, and the dashed line stands for the negative value.

be expected that there exists great magnetic anisotropy in $\text{Mn}_{12}\text{O}_{12}$ acetate.

In summary, the electronic and the magnetic properties of the $\text{Mn}_{12}\text{O}_{12}$ molecule at ground state have been investigated by the DVM with LSDA. We have found that the magnetic moments in the inner shell and the outer shell are antiferromagnetically aligned. The calculated total magnetic moment $20.0\mu_B$ for the $\text{Mn}_{12}\text{O}_{12}$ molecule is in good agreement with recent experimental data.¹¹ However, we did not find a significant difference in the occupation numbers for Mn_c and Mn_t . We attribute the large difference of magnetic moment for Mn_c and Mn_t ions to the different exchange splitting of $3d$ orbitals. The experimental observation of the strong anisotropy of $\text{Mn}_{12}\text{O}_{12}$ acetate^{10,12} has been confirmed by the strong anisotropy of the charge density and the spin density.

A comparison between a two-material and three-material magnetic current limiter

S. Young and F. P. Dawson^{a)}

Department of Electrical and Computer Engineering, University of Toronto, Toronto, Ontario M5S-3G4, Canada

M. Iwahara and S. Yamada

Department of Electrical and Computer Engineering, Kanazawa University, Kodatsuno 2-40-20, Kanazawa 920, Japan

This paper investigates the inductance versus current characteristics of a two-material and a three-material magnetic current limiter. The two-material device consists of a NdFeB permanent magnet, a high saturation flux density magnetic material, and a high saturation flux density magnetic pole piece placed on both sides of the magnet. The three-material device consists of a NdFeB permanent magnet, a high saturation flux density magnetic material, and a low saturation flux density material. Finite-element results for the three-material device agree with the results obtained using design equations. In contrast, the results obtained for the two-material device show that the transition current is overestimated and that the ratio of the maximum safe current and transition current, as well as the unsaturated inductance is underestimated. Extending the magnet beyond the adjoining surfaces improves the sharpness of the transition characteristics when the ratio of the core length to the core width is large. © 1998 American Institute of Physics. [S0021-8979(98)16211-4]

I. INTRODUCTION

Power systems especially in city centers are becoming increasingly interconnected in an effort to increase the reliability of the electric supply. This increasing interconnectivity results in raised short circuit levels, which traditional circuit breakers are straining to limit. A number of current limiting approaches such as tuned impedances, switched impedances, superconductors, series arc devices, and thermistorlike devices have been proposed in the past to address this problem.^{1,2} Unfortunately, these approaches all have reliability problems. Recently, a passive current limiting device consisting of three magnetic materials was proposed.³ The device should be reliable but would be expensive to produce. Two of these devices connected in series and in magnetic opposition to each other would provide bipolar current limiting.

This paper proposes two simplified structures, which address the concern over cost. The inductance versus current characteristic of each device is investigated. Finally, the optimal two-material and three-material device designs are compared.

II. SIMPLIFIED CURRENT LIMITER CONFIGURATIONS

The structure shown in Fig. 1(a) consists of a NdFeB permanent magnet sandwiched between the central pole faces of two high permeability, high saturation, flux density grain oriented *E* cores. The enlarged core section on either

side of the magnet is designed to confine the magnet's flux to the central core area. Most of this core section can be designed to operate out of saturation by choosing its height to be greater than a specified minimum value. The core sections with the reduced area have a coil wrapped around them. Core saturation exists when no coil current is applied. An unsaturated condition occurs if the coil current exceeds a critical value.

The second structure shown in Fig. 1(b) consists of two high permeability, high saturation, flux density *C* cores placed pole to pole. An additional structure consisting of an extended NdFeB permanent magnet sandwiched between two equally sized blocks of low saturation, flux density moderate permeability materials is centrally placed between the two *C* cores and has a coil wrapped around it.

III. DESIGN CRITERIA AND ASSUMPTIONS

The major design criteria for a current limiter are shown in Fig. 2. The objective is to maximize the ratio between the unsaturated (L_{unsat}) and saturated (L_{sat}) inductance subject to cost constraints, to extend the current range over which the unsaturated inductance value is maintained, and to maintain a uniform flux distribution in the saturated region. A uniform distribution provides a sharper transition region, at I_{knee} , between the saturated and unsaturated state.

The magnetic devices are assumed to be infinitely long in the *z* direction so as to allow a comparison between the two 2d devices and to minimize the effects of leakage flux in the *z* direction. The inductance versus current characteristics

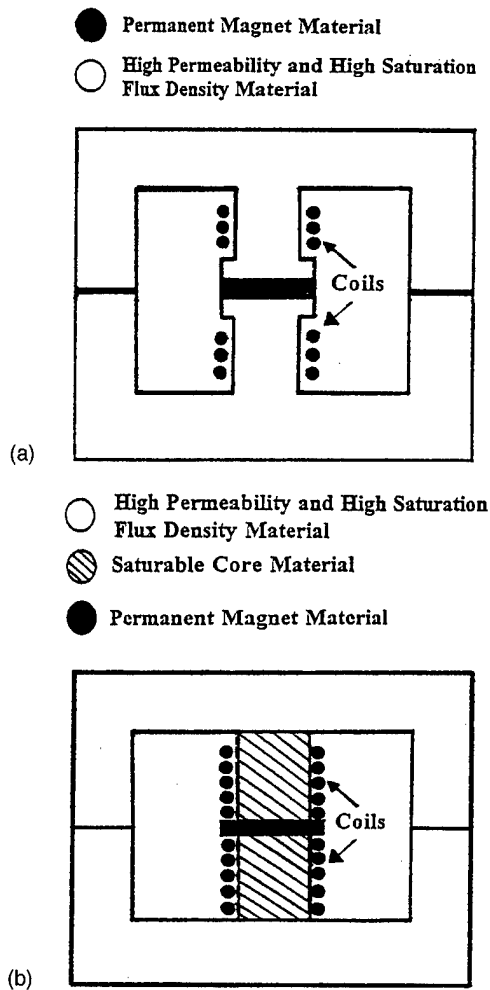

FIG. 1. Unipolar current limiters: (a) two material and (b) three material.

are obtained using Infolytica's MAGNET 5.2 finite-element analysis software package.

The two-material and three-material designs are based on the following specifications and the design equations.⁴ Functional: knee current $I_{knee}=50$ A, $I_{max}/I_{knee}=2.1$, $L_{unsat}=14$ mH, and number of turns $N=100$. Magnet parameters: remnant flux density $B_m=1.144$ T, recoil line slope $\mu_m=1.1$, and magnet length $l_{mag}=1$ cm. Central core parameters: $B_c^* A_{core}/A_{mag}=0.4$ T where B_c represents the saturation flux density of the saturable core material and A_{core} is the saturable core area. A_{mag} represents the magnet area for the two-material device and is equal to A_{core} for the three-material device. (Note: selecting a value higher/lower than

 U6 Trapezoidal focusing blocks: C is MU4; D is air.

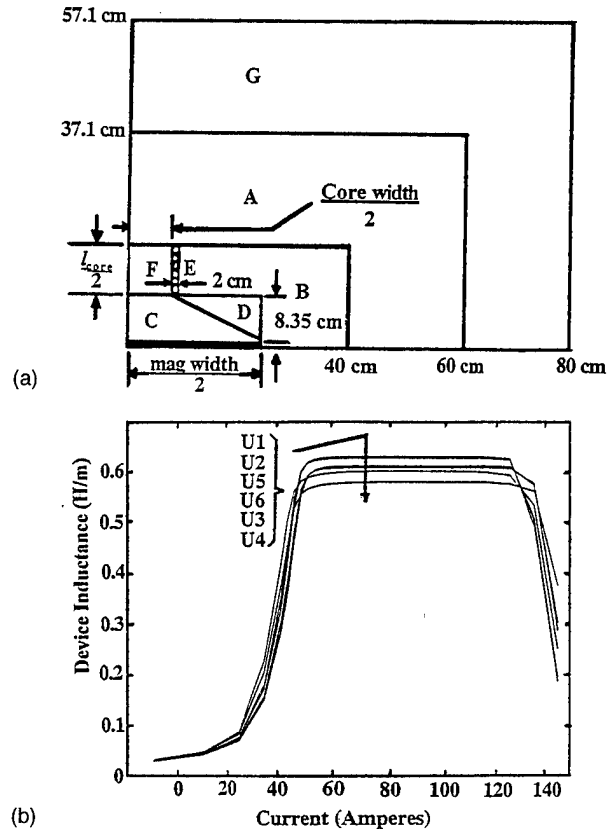

FIG. 3. Two-material current limiter; (a) geometry of one quarter of the device, and (b) inductance vs current characteristics.

0.4 T results in a higher/lower I_{max}/I_{knee} ratio but a larger/smaller magnet volume.) The choice of 0.4 T, approximately half of B_m , is a compromise. B_c for the two-material design is 1.77 T (i.e., TR66 core material). B_c for the three-material design is 0.4 T.

IV. SIMULATED INDUCTANCE VERSUS CURRENT CHARACTERISTICS

A. Two-material device

Figure 3(a) shows one quarter of the device and the tests which were performed. The purpose of these tests was to investigate the effect of the core pole face material and shape on the inductance versus current profile. Figure 3(b) shows the finite-element results for the inductance versus current characteristics. A larger leakage flux is observed with the higher permeability material, therefore, L_{unsat} is high. Tapering of the extended area section reduces the leakage flux, thus lowering the unsaturated inductance. Low permeability material does not contain the magnet flux very well. There-

FIG. 4. Three-material current limiter: (a) geometry of one quarter of the device, and (b) inductance vs current characteristics.

fore, the saturated-to-unsaturated transition occurs at a lower knee current and is less well defined. The ratio $I_{\text{max}}/I_{\text{knee}}$ increases due to the reduced flux confinement.

B. Three-material device

Figure 4(a) shows one quarter of the device and the tests which were performed. The purpose of these tests was to determine the effect of the core length and magnet extension on the inductance versus current profile. Figure 4(b) shows the finite-element results for the inductance versus current characteristics. The core length influences only the saturated inductance value. The magnet extension improves the sharpness of the transition from the saturated to the unsaturated state, especially if the core length to core width ratio is large.

C. Comparison of the two-material and three-material current limiter

Both devices were designed according to the specifications in Sec. III and the stipulation that $L_{\text{unsat}}/L_{\text{sat}} = 40$. TR66 material is used for the E core on the two-material device. The extended area section is trapezoidal in shape so as to

FIG. 5. Comparison of a two-material and three-material inductance vs current characteristics.

reduce the leakage inductance. This improves the sharpness of the transition at I_{knee} and increases the $L_{\text{unsat}}/L_{\text{sat}}$ ratio.

The width and thickness of the magnet in contact with the core material for both designs is 40 and 1 cm, respectively. In the three-material case, the magnet extends an additional 5 cm away from the outside surface of the core material. The core length and core width are 40 cm for the three-material device and 10 cm for the two-material device. The height of the extended area sections for the two-material device is 29 cm.

Figure 5 shows the inductance versus current characteristics for the two-material and three-material device. The results of the design equations for the three-material device are in agreement with finite-element results shown in Fig. 5. In contrast, the results of the design equations for the two-material device show that I_{knee} is overestimated, the ratio $I_{\text{max}}/I_{\text{knee}}$ is underestimated, and L_{unsat} is underestimated. Also, the transition characteristic for the two-material device is poorly defined. Thus, under normal ac operating conditions, the flux density in the core of the two-material device cycles between an unsaturated value and a saturated value. This results in a large minor hysteresis loop area, and consequently, high operating losses.

V. CONCLUSIONS

Finite-element results for the three-material current limiting device agree with the results obtained using design equations. In contrast, the results obtained for the two-material current limiting device show that the transition current is overestimated, and that the ratio of the maximum safe current, and the transition current, as well as the unsaturated inductance are underestimated. Extending the magnet beyond the adjoining surfaces improves the sharpness of the transition characteristics when the ratio of the core length to the core width is large.

Reversible and irreversible components of tensor magnetization and magnetostriction

F. Liorzou, Y. Yu, and D. L. Atherton^{a)}

Department of Physics, Queen's University, Kingston, Ontario K7L 3N6, Canada

Tensor magnetostriction and magnetization hysteresis loops for a 25 mm ferrite magnet cube were measured. These describe the magnetization properties and reflect the anisotropy of the system. The sample investigated allowed the magnetization to be interpreted in terms of a magnetization vector rotation process and described by the Stoner–Wohlfarth model. The reversible and irreversible components were extracted for both the magnetostriction and magnetization tensors. Up to now, very few direct measurements of these reversible changes in strain have been reported. The different magnitudes of reversible magnetization and magnetostriction are analyzed and explained qualitatively by a representation involving both magnetization and magnetostriction processes. The magnetostrictive effect is taken into account quite simply by considering a demagnetized sphere distorted into an ellipsoid of revolution when saturated. The ellipsoid will rotate as the magnetization vector according to the Stoner–Wohlfarth model. Two cases are illustrated depending on the easy axes location. These explain the experimental results obtained with the ferrite sample.

© 1998 American Institute of Physics. [S0021-8979(98)16311-9]

I. INTRODUCTION

Magnetostrictive effects in polycrystalline samples are closely associated with changes of magnetization, and depend on the direction of the bulk easy axis, on the magnetization mechanisms (domain wall motion, magnetization vector rotation), and also on the reversible or irreversible processes. Here the influence of some of those parameters is reported.

- (1) Nine element tensor magnetic hysteresis loops and magnetostriction loops were measured on a ferrite permanent magnet cube. Previous articles^{1–3} have already shown the significance of obtaining tensor measurements which also define the sample bulk easy axes.
- (2) Our specimen contains highly oriented fine Ba particles. The grain size is small enough to assume that the whole magnetization is provided by moment rotation.
- (3) Reversible magnetization and also magnetostriction were separated experimentally using incremental field reversals. The different magnitudes of the reversible magnetization and magnetostriction tensor elements are analyzed and explained qualitatively.

II. EXPERIMENTS

The sample investigated is an Indiana Indox 5 ferrite permanent magnet cube (25.5 mm size) with nominal composition $\text{BaO}_6\text{Fe}_2\text{O}_3$. The cube sample was placed between the closed pole pieces of a variable gap electromagnet. Three 20-turn flux coils, as well as a strain gauge, were installed on the cube to measure magnetization and magnetostriction, respectively (Fig. 1). This method ensures that the results are comparable. The experimental apparatus and measurement technique have been described previously.^{1–3} In order to es-

timate the contribution of reversible and irreversible processes, small field reversals of dH are made every three points while the magnetization and magnetostriction major loops are described. Those small incremental reversible changes are then summed to give the reversible component. This operation is very sensitive to noise and requires accurately measured experimental loops. The irreversible parts are then deduced by subtracting the reversible components from the total.

A. Magnetization, reversible, and irreversible components

Only the diagonal components of the magnetization tensor are reported presently (the off diagonal components are much smaller).³ Figure 2 shows the reversible and irreversible magnetization components. It has been shown previously^{1,3} that the tensor enables the sample's easy axis to be located close to the z axis (as represented schematically in Fig. 1). This gives rise to the measurement of a very square zZ magnetization loop with the largest irreversible process.

B. Magnetostriction, reversible, and irreversible components

Because dimensional change in one direction is accompanied by a comparable change in the transverse direction, the magnetostriction is also measured in the x , y , and z directions, for each direction of the applied field. The result is then presented in the form of a 3×3 matrix in Fig. 3, which represents the complete magnetostriction tensor. As mentioned previously, this sample, composed mainly of single domain grains, gives the magnetostriction component of rotational magnetization.

Separation of reversible and irreversible magnetostriction components has been achieved by the method described above. This is depicted in Fig. 4.

^{a)}Electronic mail: Atherton@physics.queensu.ca

FIG. 1. Schematic showing 25 mm ferrite cube and associated X , Y , and Z coordinate system. For field applied in the x direction, λ_{xX} , λ_{xY} , and λ_{xZ} represent the three components of magnetostriction. The coils X , Y , and Z allow measurement of magnetization in each direction.

The tensor magnetostriction loops also reflect dependence on the easy axis of the sample. In particular, the zZ element shows a sudden variation of magnetostriction at the coercive field, as evident in Fig. 4. This phenomenon is purely irreversible. This sudden irreversible rotation is also observed in the corresponding zZ element of magnetization. Such behavior is not observed in the other elements.

Generally speaking, one can note the high rate of reversible compared to irreversible events involved in magnetostriction. At first glance, this result is surprising in view of the corresponding reversible and irreversible magnetization rates.

III. INTERPRETATION

The classical model used to explain rotational magnetization is the Stoner–Wohlfarth model.⁴ This model states that, due to the anisotropy energy (here the magnetocrystalline energy), moment rotation under positive to negative field variations consists of reversible and irreversible portions. The latter corresponds to switching of magnetization due to the presence of metastable energy states. The sudden change of magnetostriction observed in the zZ element can then be interpreted as irreversible switching of moments, which is, again according to the model, particularly significant when the applied field and easy axes directions are close to each other. So this confirms the correctness of the sample's bulk easy axis direction determined elsewhere.

It was noted that reversible magnetostriction comprises the main magnetostriction component. Irreversible switching of moments does not provide such a high rate of magnetostriction as magnetization. This feature can be interpreted as follows: Assume that under the action of the magnetostric-

FIG. 2. Total, reversible (thick line) and irreversible (dotted line) component of tensor magnetization diagonal elements. The field is applied respectively in the three orthogonal directions (x, y, z). The horizontal axis is the magnetic field in kA/m, the vertical axis the magnetization in A/m (10^{-5}).

FIG. 3. Measured tensor magnetostriction for the Indox 5 cube. Labels xX , xY , and xZ represent magnetostriction components measured along the x , y , and z directions with magnetic field in the x direction, and so on. In each figure, the horizontal axis is the magnetic field in kA/m and the vertical the magnetostriction in microstrain (10^{-6}).

tive effect, the particles that compose the sample spherical in shape when demagnetized, become elongated in the direction of magnetization after magnetization. The ellipse so defined rotates according to the angle between the magnetization and the varying applied field. The magnetostriction is then deduced by calculating the change of length in a specific direction.

Two completely different cases are examined corresponding to the experimental situation:

FIG. 4. Reversible (thick line) and irreversible (thin line) component of tensor magnetostriction elements. In each figure, the horizontal axis is the magnetic field in kA/m and the vertical axis is the magnetostriction in microstrain (10^{-6}).

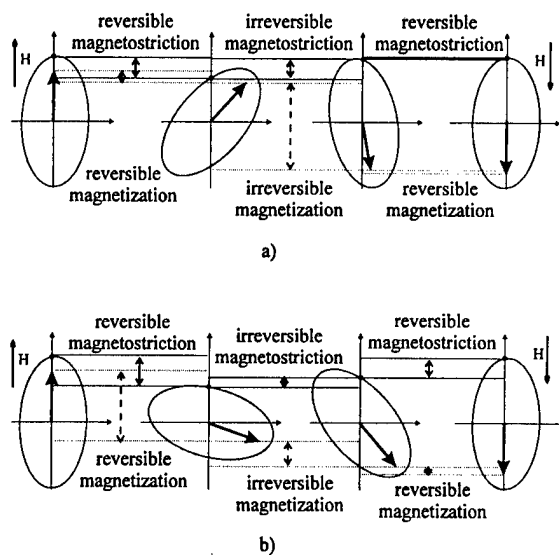

FIG. 5. (a) Magnetization and magnetostriction processes when the easy axis is close to the field direction. The magnetostrictive effect is illustrated simply by considering a demagnetized sphere distorted into an ellipsoid when saturated. The ellipsoid will rotate as the magnetization vector (symbolized by an arrow). (b) Magnetization and magnetostriction processes when the easy axis is nearly perpendicular to the field direction.

- (1) when the easy axis is close to the field direction (i.e., in the z direction in the ferrite sample);
- (2) when the easy axis is nearly perpendicular to the magnetic field direction (i.e., in the x or y direction).

Let us first examine the first case [Fig. 5(a)]. Depending on the magnitude of the field (positive to negative values), different stages of the magnetization process provided by the Stoner–Wohlfarth model are shown. The arrows indicate the magnetization direction calculated by the model while the ellipse represents the magnetostrictive effect hypothesized to elongate the spherical particle in the direction of magnetization (the actual elongation is proportionally much smaller than represented). The figure shows clearly the different rates of both reversible and irreversible magnetostriction and magnetization events. A gradual reversible rotation of the mo-

ment takes place first and, at a certain critical field, an irreversible jump occurs. This discontinuity is observed clearly in the zZ element of magnetization and in smaller amount in the zZ element of magnetostriction. So, during the process (which describes a half loop), the magnetostriction shows a comparable rate of reversible and irreversible events, while the irreversible rate of magnetization is much higher than the reversible one. These features are observed in the experimental data for this situation (all the labelled z elements of magnetostriction and magnetization).

In the case where the easy axis is nearly perpendicular to the field direction, illustrated in Fig. 5(b), the irreversible magnetostriction becomes very small. For the magnetization, the reversible events also become dominant, the irreversible part, however, is still present. Again, the experimental loops show this behavior (the labelled x , and y subfigures in the magnetostriction tensor and the x and y magnetization loops).

IV. CONCLUSION

Both tensor magnetization and magnetostriction have been measured in a ferrite cube sample. The magnetization mechanism is a Stoner–Wohlfarth type vector rotation.

Reversible and irreversible components of magnetization and magnetostriction have been extracted. The different magnitudes of these components have been analyzed and explained qualitatively by a representation involving both magnetization and magnetostriction processes. The rotating ellipse, used to represent the magnetostrictive effect in a particle during magnetization, seems to be appropriate and helpful for interpreting the experimental results.

Fundamental study for rosary-shaped magnetic actuators

H. Saotome^{a)} and K. Sakaguchi

Faculty of Engineering, Chiba University, Inage, Chiba 263, Japan

Rosary-shaped magnetic actuators are proposed. The actuators consist of multiple permanent magnet cubes connected in a queue or in a circle. By applying the magnetic field to the magnet cubes, the actuators are supposed to move in liquid and convey medicine in a human body. For the first stage, this article shows the fundamental analysis and experimental results of controlling one-magnet motions. We studied motions of a magnet of two poles, put in water, where the magnet was equipped with a float. The floating magnet was column shaped with a 10 mm diam and 6 mm height. We have succeeded in independently fixing the position and angle of the magnet by controlling the currents flowing in two separate coils. © 1998 American Institute of Physics. [S0021-8979(98)16411-3]

I. INTRODUCTION

Magnets made of Nd-Fe-B material have a large energy product. With the development of these strong magnets, various types of magnetic actuators can be produced. We propose magnetic actuators with magnet cubes connected in a queue or in a circle, as shown in Fig. 1. The actuators are driven by the controlled magnetic field. The size of each magnet element can be reduced to millimeter range and more, therefore, it is possible that the actuators may work in a human body, such as in the digestive and circulatory systems. The driving field is generated by the coil currents outside the body.

In order to realize the actuators in Fig. 1, for the first step, we studied how to control the position and angle of one magnet by the currents flowing in two separate coils. Its method and experimental results are shown in this article.

II. MOTION OF A MAGNET

A. Position and angle fixation

Assuming a magnet whose magnetic moment is \mathbf{M} , the force \mathbf{F} and the torque \mathbf{T} of the magnet, generated by the magnetic field \mathbf{H} , are given by

$$\mathbf{F} = (\mathbf{M} \cdot \text{grad}) \mathbf{H} \quad (1)$$

and

$$\mathbf{T} = \mathbf{M} \times \mathbf{H}, \quad (2)$$

respectively.^{1,2} The magnet moves toward the position where the magnetic field is maximum and faces the direction of the magnetic field. The torque is proportional to the magnetic field while the force is proportional to its gradient. From Eqs. (1) and (2) it is found that the force and torque on the magnet can be independently controlled by the magnetic field distribution around the magnet.

We assumed x - y coordinates and put a magnet on the x axis, as shown in Fig. 2. The magnetic field is generated by two separate coils shown in Fig. 3. Figure 4 shows calculated magnetic field distributions on the x axis, given by control-

ling the currents I_1 and I_2 of the coils. The values of the currents are shown by $[I_1, I_2]$ in Fig. 4. The depicted magnetic field $H(x)$ is of the x direction and calculated by

$$H(x) = \frac{nI_1 a^2}{2\{a^2 + (x+d)^2\}^{3/2}} + \frac{nI_2 a^2}{2\{a^2 + (x-d)^2\}^{3/2}}, \quad (3)$$

where n is the number of turns of the coils.

Because the angle (θ) of the magnet with respect to the x axis is not controlled by $H(x)$ only, we used the geomagnetic field as the field of the y direction, i.e., $H(x)$ is perpendicular to the geomagnetic field H_g , which is uniformly distributed in the space around the magnet. As a result, θ is determined by

$$\theta = \tan^{-1} \left\{ \frac{H_g}{H(x)} \right\}, \quad (4)$$

i.e., the fixation of θ is carried out by controlling the magnitude of $H(x)$. On the other hand, the force of the x direction is given by

$$F = M \cos \theta \frac{\partial H(x)}{\partial x}. \quad (5)$$

By the force, the magnet moves to the position where

$$\frac{\partial H(x)}{\partial x} = 0. \quad (6)$$

From Eqs. (4), (5), and (6), it is found that the position and angle of the magnet can be controlled by the $H(x)$ distribution, which is generated by I_1 and I_2 .

When we want to carry out the fixation of the position and angle of the magnet, the values of I_1 and I_2 , corresponding to the goal, are not analytically obtained with Eqs. (3), (4), and (6). However, it is observed from Fig. 4 that the peak position of the magnetic field is approximately determined by the ratio

$$r = \frac{I_1}{I_1 + I_2}, \quad (7)$$

FIG. 1. Proposed magnetic actuators. (a) Queue-shaped type and (b) circular type.

FIG. 2. A magnet put on the x - y coordinates.

FIG. 3. Two separate coils for generating magnetic field distribution.

FIG. 4. Calculated magnetic field distributions on the x axis. The number of turns of the coils, $n=50$ (turns), the radius of the coils, $a=53$ (mm), and the distance between the coils, $d=19$ (mm).

FIG. 5. (a) A floating magnet of two poles. (b) The magnet is put in a pipe and floating on water.

FIG. 6. Position control by the current ratio.

and the magnitude of the magnetic field is proportional to the total current

$$I_t = I_1 + I_2. \quad (8)$$

This result implies that we can control x and θ by r and I_t , respectively.

B. Implementation

In order to demonstrate the control of the position and angle by experiments, a magnet of two poles, equipped with a float, was made, as shown in Fig. 5(a). The magnet is column shaped with a 10 mm diam and 6 mm height. The magnet is put in a transparent pipe and floating on water, as shown in Fig. 5(b). The pipe is put in perpendicular to the geomagnetic field, i.e., it is set on the x axis in Fig. 3. We made the radius of the coils, $a=53$ (mm), and the distance of the coils, $2d=38$ (mm).

Figure 6 shows the calculated and experimental results of x and θ when the current ratio r has been changed and the total current is kept at $I_t=300$ (mA). The calculated and experimental results almost coincide with each other. It is also found from Fig. 6 that the position x has been controlled by the current ratio r , while the angle θ is almost kept at a constant value.

Figure 7 shows the calculated and experimental results of x and θ when the total current I_t has been changed and the

FIG. 7. Angle control by the total current.

current ratio is kept at $r=0.6$. The calculated and experimental results almost coincide with each other. It is also found from Fig. 7 that the angle θ has been controlled by the total current I_t , while the position x is almost kept at a constant value.

III. CONCLUSION

As shown above, we have succeeded in independently controlling the position and the angle of a two-pole magnet

by the current ratio and the total current of two separate coils, respectively. This technique will be the basis of controlling the proposed actuators in Fig. 1.

The design and analysis of axial field multipole impulse magnetizing fixtures

C. D. Riley

Magnetic Systems Technology Ltd., Sheffield Technology Park, 60 Shirland Lane, Sheffield, S9 3SP United Kingdom

G. W. Jewell and D. Howe

Department of Electronic and Electrical Engineering, The University of Sheffield, Mappin St. Sheffield, S1 3JD United Kingdom

A methodology for the design of fixtures for the multipole magnetization of axially magnetized permanent magnet rings is presented. The methodology, which is based on three-dimensional analytical field calculation techniques, embraces the calculation of the fixture electrical parameters, the electrical simulation of the fixture performance and the calculation of the level of saturation achieved in the permanent magnet. The methodology is validated by means of an experimental case study on a 6 pole isotropic NdFeB magnet ring. © 1998 American Institute of Physics. [S0021-8979(98)36211-8]

INTRODUCTION

Axially magnetized multipole permanent magnet rings are widely used in devices such as axial-field machines for radiator cooling fans, electric wheel chair motors, office equipment and automotive electric window mechanisms.^{1,2} This paper addresses a key stage during the device manufacture, viz. the multipole magnetization of the magnet ring by means of capacitor discharge impulse magnetization. Schematics of the typical forms of single and double sided, axial field multipole magnetizing fixtures are shown in Fig. 1. Two-dimensional magnetic field calculation techniques have been employed in the design of axial field multipole magnetizing fixtures with some degree of success by a number of authors.^{3,4} However, in many cases, particularly those involving magnet rings with a relatively large ratio of outer to inner diameter, and fixtures in which the end-windings are located in close proximity to the outer edge of the magnet ring, recourse to three-dimensional analysis is necessary.

The design methodology presented in this paper is applicable to a wide range isotropic and anisotropic permanent magnet materials. However, the focus in this paper is on isotropic NdFeB bonded magnets since they are particularly difficult to multipole magnetize, both in terms of the high magnetizing field strengths required to ensure saturation (typically 2500 kA/m), and the isotropic behavior which dictates that the magnetizing field distribution must conform to the desired orientation of the final remanent magnetization.

DESIGN METHODOLOGY

The design methodology is based on a scanning approach in which the relative merits of a large number of candidate fixture designs are compared. A given axial field fixture/magnetizer system can be fully described by a relatively small number of parameters, viz. the basic topology (i.e., single or double sided), the number of conductors per pole, the arrangement of the conductors at each pole, the conductor diameter, the radial overhang of the conductors, and the magnetizer capacitance and

initial voltage. The performance of a particular combination of parameters is predicted in a number of stages:

- (i) Calculation of fixture inductance and initial resistance.
- (ii) Calculation of the peak current and temperature rise during the impulse period.
- (iii) Calculation of the localized magnetizing field at a number of points within the magnet volume.
- (iv) Calculation of the level of saturation and degree of alignment achieved in the magnet.

The cornerstone of the design methodology is the calculation of the three-dimensional magnetizing field distribution produced by a given design of magnetizing fixture. This is the basis for determining both the fixture inductance and the level of saturation achieved in the magnet. An analytical field calculation technique is employed, since air-cored magnetizing fixtures generally represent a good approximation to a linear problem domain.⁴ The field calculation technique is based on the superposition of the field produced by the individual straight and curved conductors segments from which a multipole fixture is composed. The coordinate systems used in the calculation of the flux density at a general point P due to straight conductors and arc segments are shown in

FIG. 1. Schematic representations of single and double-sided axial field multipole magnetizing fixtures.

FIG. 2. Three-dimensional coordinate system for the calculation of flux density at the general point P due to a finite length straight conductor.

Figs. 2 and 3, respectively. The components of flux density produced by the conductor segments at the general point P when carrying a current I , are given by Eqs. (1) and (2), respectively,

$$\begin{aligned} B_r &= B_m \frac{(h-z)}{r_0} \sin \phi, \\ B_\phi &= B_m \frac{(h-z)}{r_0} \cos \phi, \\ B_z &= B_m \frac{r \sin \phi}{r_0}, \end{aligned} \quad (1)$$

where

$$\begin{aligned} B_m &= \frac{\mu_0 I}{4\pi r_0} \left[\frac{(z_0 + (L/2))}{[r_0^2 + (z_0 + (L/2))^2]^{1/2}} - \frac{(z_0 - (L/2))}{[r_0^2 + (z_0 - (L/2))^2]^{1/2}} \right], \\ B_r &= \frac{\mu_0 I a z}{4\pi} \int_{\Psi_1}^{\Psi_2} \frac{\cos(\Psi - \phi)}{\bar{R}^3} d\Psi, \\ B_\phi &= \frac{\mu_0 I a z}{4\pi} \int_{\Psi_1}^{\Psi_2} \frac{\sin(\Psi - \phi)}{\bar{R}^3} d\Psi, \\ B_z &= \frac{\mu_0 I a}{4\pi} \int_{\Psi_1}^{\Psi_2} \frac{a - r \cos(\Psi - \phi)}{\bar{R}^3} d\Psi, \end{aligned} \quad (2)$$

FIG. 3. Three-dimensional coordinate system for the calculation of flux density at the general point P due to a finite length arc segment conductor.

where

$$\bar{R} = [a^2 + r^2 + z^2 - 2ar \cos(\Psi - \phi)]^{1/2}.$$

The integral terms in each of the above expressions are evaluated numerically by means of a second order integration. The net resultant field at a given point can be calculated by a summation of the contributions of each elemental conductor, with due account of the individual current polarities.

The overall fixture inductance is calculated from a summation of the flux linkage of each winding layer. This in turn, is evaluated by integrating the analytically calculated axial component of flux density over at a number of discrete points on a surface which covers one pole and is located at the same axial position as the winding layer under consideration. To ensure that an adequate number of discrete points are used, an algorithm is employed which automatically increases the number of summation points until the fractional change in the predicted value of inductance falls below a prespecified tolerance. The fixture resistance is given by

$$R_{\text{fix}} = \frac{\left[\sum_{j=1}^N p \left(2l_{rj} + \frac{2\pi}{p} (r_{oj} + r_{ij}) \right) \right] \rho_{\text{Cu}}}{A_c},$$

where N =number of coils per pole, p =number of poles, l_{rj} =length of radial conductors, r_{ij}, r_{oj} =inner, outer end-winding radii, A_c =cross sectional area of conductor, ρ_{Cu} =electrical resistivity of copper.

The peak current and temperature rise of a given fixture/magnetizer combination is predicted by an electrical simulation previously developed for the design and analysis of multipole radial magnetizing fixtures, in which due account is taken of the change in fixture resistance caused by heating during the impulse period.³

The three-dimensional analytical field calculation technique can be used to determine the magnitude and orientation of the applied magnetizing field strength at a large number of points within the magnet. Whereas neglecting the nonlinearity in calculating the level of applied field is valid in a large number of cases, due account of the self-demagnetizing effect must be taken in calculating the net magnetizing field strength to which a region of the magnet is exposed. This is achieved by using an established technique previously proposed by the authors.³

FIG. 4. Measured dependency of the remanence and intrinsic coercivity of Plastiform 2004D isotropic NdFeB on the magnitude of the initial magnetizing field strength.

TABLE I. Fixture design parameters and measured performance.

Conductors per pole	6	Predicted time to peak	258 μ s
Conductor diameter	2.0 mm	Measured peak current	23.6 kA
Capacitor voltage	2.8 kV	Measured time to peak	255 μ s
Volume saturation	97.2%	Predicted resistance	34.1 m Ω
Orientation	97.3%	Predicted inductance	15.4 μ H
Temperature	135 $^{\circ}$ C	Measured resistance	36.0 m Ω
Predicted peak current	23.1 kA	Measured inductance (at 1 kHz)	14.8 μ H

Having established the distribution and orientation of the localized net magnetizing field, the level of saturation can be calculated from material characteristics such as those in Fig. 4 which shows the measured dependency of the remanence and intrinsic coercivity on the magnitude of the magnetizing field strength. A useful global figure of merit for comparing different fixture designs is the percentage volume saturation, which is defined as the integral over the magnet volume of the products of the remanence and coercivity achieved at each discrete point as a percentage of the maximum obtainable values in a fully saturated magnet.⁵ In order to quantitatively compare the degree of axial orientation of the magnetization, a further figure of merit can be employed, viz. the percentage axial alignment, which is a weighted average of the degree of alignment at each discrete point.

CASE STUDY

In order to validate the various constituent calculation techniques, and to demonstrate the utility of the overall design methodology, a fixture to magnetize a 6-pole isotropic NdFeB magnet ring was designed and constructed. The magnet ring (inner diameter 40 mm, outer diameter 120 mm), comprised 5 layers of 1 mm thick Arnold Engineering Plastiform 2004D flexible bonded NdFeB sheet, the characteristics of which were shown previously in Fig. 4. The fixture was designed to operate with an existing 10 kJ capacitor discharge magnetizer (0–3 kV continuously variable, 0–2200 μ F in 445 μ F increments), with a rated maximum current of 45 000 A.

FIG. 5. Measured and predicted profiles of the normal component of flux density 0.5 mm above the magnet surface (circumferential profile at a radius of 40 mm).

In order to produce as near an ideal axial orientation of magnetization within the isotropic magnet ring, a double-sided fixture was selected since this topology of fixture inherently produces a better axially aligned magnetizing field than a single-sided fixture. An axial clearance of 1 mm was specified between the leading conductors and the surface of the magnet in order to provide sufficient containment for the winding, while a maximum conductor temperature of 200 $^{\circ}$ C (from a 20 $^{\circ}$ C starting ambient) was specified.

Following extensive scanning of the fixture parameters, the fixture design whose parameters are shown in Table I was identified as being the most suitable.

The measured inductance and resistance of the fixture were in good agreement with the predicted values, as shown in Table I.

Following the magnetization of the magnet ring, the normal component of flux density at a distance of 0.5 mm from the magnet surface was measured using a Hall effect gaussmeter equipped with a probe with an element of diameter 0.2 mm. In order to confirm that the measured flux density profiles correspond to a fully saturated magnet with the desired orientation, a three-dimensional magnetostatic finite element calculation of the field produced by an idealized magnet with same demagnetization characteristic was performed, i.e., a magnet which is fully saturated throughout its volume with an entirely axial direction of magnetization. The finite element calculation was performed using MEGA.⁶ Figure 5 shows the excellent correlation between the measured and predicted flux density along a circumferential profile spanning one pole at a radial distance of 40 mm from the center of the magnet ring. This demonstrates, that as predicted during the design synthesis, the selected fixture does indeed produce a very close approximation to a fully saturated, fully axially orientated 6 pole magnet ring. This demonstrates albeit on a rather large magnet ring, that by careful design of the fixture, the properties of a multipole magnetized ring can often show negligible departure from those which can be achieved with individually magnetized segments. However, it is likely that this departure from an idealized orientation will inevitably become more pronounced as the magnet size is reduced.

Fabrication of a micromotor driven by electromagnetic vibration

T. Honda^{a)} and J. Yamasaki

Kyushu Institute of Technology, 1-1 Sensuichou, Tobata-ku, Kitakyushu 804, Japan

A new electromagnetic rotary mechanism utilizing a friction drive is proposed. An electromagnetic vibration excited on a permanent magnet is converted to a rotary movement through a frictional force. A trial motor, composed of a magnet rotor with inclined legs and an excitation coil, was fabricated and successfully operated. A no-load revolution speed up to 400 rpm and a reversible rotation were achieved. © 1998 American Institute of Physics. [S0021-8979(98)49311-3]

I. INTRODUCTION

During the last decade there has been much work towards realizing micromotors for the microelectromechanical systems. Most of these efforts focused mainly on electrostatic side-drive micromotors and variable reluctance magnetic ones, which, however, face a serious problem. Their very high revolution speed over 10^4 rpm and poor torque are unacceptable for practical applications.

To solve this problem and realize the practical micromotor, two rotary mechanisms with large torque at a low revolution speed have so far been proposed. One is a wobble mechanism,^{1,2} in which a cylinder rotor rolls inside a stator with either electrostatic or electromagnetic forces. The other is a friction drive mechanism, which converts a mechanical vibration to a rotary movement through a frictional force. Several kinds of ultrasonic micromotors based on a piezoelectric vibration have been proposed,^{3,4} but only a few attempts have been made at the other friction drive motors.

In this study, we proposed a new magnetic micromotor utilizing the friction drive mechanism, which can convert the electromagnetic vibration to the rotary movement. In this article, the structure, principle, and no-load characteristics of the trial motor are described.

II. DEVICE STRUCTURE

Figure 1(a) shows a side view of a trial-fabricated friction drive motor. It consists of a cylinder rotor, 5 mm in diameter and 3 mm in height, and a small solenoid coil. The rotor is a NdFeB magnet, magnetized along the height direction, and has four elastic legs on the base. The legs, made of a polyethylene terephthalate (PET) film with a thickness of 0.1 mm, are inclined at a certain angle, θ , arranged equally round the perimeter of the rotor base, as shown in Fig. 1(b). The size of the legs is 1.5 mm long and 1.25 mm wide. In this study, we examined two different inclined angles: $\theta = 50^\circ$ and 85° . The rotor is laid on a cover glass fixed on the end of the coil. In order to vibrate the rotor by using the attractive force, an ac current biased with a dc current is applied to the coil. The value of the dc current is the same as the amplitude of the ac current. Thus the rotor is magnetically fixed on the coil end without any external mechanical preload.

III. OPERATION PRINCIPLE

Let the z axis be the vertical direction in Fig. 1. The vertical force, F_z , acting on the magnet with magnetization, M_z , and volume, V , is given by

$$F_z = M_z \cdot \int dH_z/dz \cdot dV, \quad (1)$$

where H_z is the z component of the magnetic field produced by the solenoid coil. The attractive force by the sinusoidal current biased with the dc current can be represented by

$$F_z(t) = -F_0 z (1 + \sin 2\pi f t)/2, \quad (2)$$

where $F_0 z$ is the maximum attractive force in the z direction and f is the excitation frequency. Since the legs act as elastic springs, the rotor vibrates downward and upward according to the attractive force. At the same time an angular movement occurs due to the frictional force of the tip of the legs.

FIG. 1. Schematic view of the trial motor.

^{a)}Electronic mail: honda@mag.ele.kyutech.ac.jp

FIG. 2. Relation between the normal reaction and the frictional force.

Before turning to a closer consideration about the angular movement, we must describe the sliding condition of the leg during the downward motion. Figure 2 shows the relation between the normal reaction, N , and the frictional force, μN , at the tip of the leg when the rotor starts displacing downward. Here μ is the frictional coefficient. Taking account of the moment equilibrium about the hinge, the following relation is found:

$$\theta = \tan^{-1}(1/\mu). \quad (3)$$

If $\theta \geq \tan^{-1}(1/\mu)$, the tip of the leg is self-locked and cannot slide during the downward motion. On the other hand, if $\theta < \tan^{-1}(1/\mu)$, the tip slides in the right-hand direction. In general, μ is 0.2–0.5 and, therefore, the angle that satisfies Eq. (3) may be 60° – 80° . We will consider the predicted behavior of the rotor in the following two cases.

A. $\theta \geq \tan^{-1}(1/\mu)$

Figure 3 illustrates the predicted behavior for $\theta \geq \tan^{-1}(1/\mu)$. At a low frequency range, the rotor vibrates

FIG. 3. Predicted behavior of the leg for $\theta \geq \tan^{-1}(1/\mu)$.FIG. 4. Predicted behavior of the leg for $\theta < \tan^{-1}(1/\mu)$.

around the contact point without sliding and remains at the original position, as shown in Figs. 3(a) and 3(b). At higher frequencies, however, the tip slides in the left-hand direction during the upward motion because the increase in the z component of the acceleration of the vibration decreases the normal reaction and hence reduces the frictional force. If the z component of the acceleration is larger than that of the gravity, the tip may take off from the stator and touch down to the left side, as shown in Fig. 3(c). Thus, the rotor moves in the left-hand direction at higher frequencies.

B. $\theta < \tan^{-1}(1/\mu)$

Figure 4 illustrates the predicted behavior for $\theta < \tan^{-1}(1/\mu)$. During the downward motion, the leg slides in the right-hand direction, as shown in Fig. 4(a). During the upward motion, on the other hand, two different behaviors are possible, depending on the frequency, as shown in Figs. 4(b) and 4(c). At a low frequency range, the tip is pushed against the stator and the rotor stands up around the tip without sliding. Thus the motor moves in the right-hand direction. At a high frequency range, the tip moves in the left-hand direction for the same reason as in Fig. 3(c). In this case, the rotational direction depends on the difference of the sliding distance between upward and downward motions.

IV. RESULTS AND DISCUSSION

In this study, we examined the no-load revolution speed when $F_0 z$ was approximately 120 mN. Figure 5 shows the revolution speed for $\theta = 50^\circ$ and 85° as a function of the excitation frequency. The sign of the revolution speed means the rotational direction, in case of a plus sign, rotates in the left-hand direction in Fig. 2.

First, we focus on the result for $\theta = 85^\circ$. The motor hardly rotated below 600 Hz though the slight rotation in the negative direction was observed around 200 Hz. The rotation in the positive direction suddenly occurred at 600 Hz and

FIG. 5. Revolution speed as a function of the excitation frequency.

reached a peak of 400 rpm at the same time. This sudden rotation was caused by the mechanical resonance in the z direction. Afterwards the revolution speed decreased with increasing the frequency and then exhibited a second peak around 1.2 kHz, which may be due to the resonance in the angular direction.

On the other hand, the result for $\theta = 50^\circ$ showed a reversible rotation. At lower frequencies below 200 Hz, the motor rotated in the negative direction, as expected, and the revolution speed increased with increasing the frequency. The maximum revolution speed of 160 rpm was obtained at 200 Hz. But the rotation stopped at the range 200–300 Hz because the amplitude of the vibration in the z direction was too large to rotate stably. Afterwards, the rotational direction

changed to the positive direction with the increasing the frequency and reached a peak of 230 rpm at 480 Hz. The rotation in the positive direction at higher frequencies suggests that the sliding distance is larger during the upward motion than during the downward motion.

Finally, we must remark on the torque of the motor. The torque measured was only the order of 10^{-5} Nm. Of course, the torque can be improved by increasing the electromagnetic attractive force. One promising method would be to insert the core into the driving coil. This point is currently under investigation.

V. CONCLUSIONS

We have proposed a new type of rotary micromechanism which can convert the electromagnetic vibration to the rotary movement through the frictional force of the inclined legs. The trial motor based on this mechanism successfully rotated and exhibited unique characteristics depending on the inclined angle of the legs. The unique characteristics obtained suggest that the mechanism is useful as a driving principle of a micromotor.

New permanent magnet couplings for screwing devices

L. Quéllec, V. Lemarquand, and G. Lemarquand

Laboratoire d'Electrotechnique et de Magnétisme de Brest, IUT, Rue de Kergoat, 29287 Brest, France

The use of permanent magnet coaxial synchronous couplings in screwing devices allows one to adjust the screwing torque very precisely, but the symmetrical behavior of classical systems always leads to a partial unscrewing. This article shows that the dissymmetry of this behavior can be enhanced only by the modification of the shape of the magnets stuck on the rotors. The consideration of some basic geometrical parameters (number and length of poles) and the application of rules to reach the dissymmetry lead to improved couplings for screwing devices.

© 1998 American Institute of Physics. [S0021-8979(98)17011-1]

I. INTRODUCTION

The permanent magnet couplings¹ allow transmitting forces and torques without any contact between interacting parts. The use of distance attraction forces between magnets makes it possible to obtain total watertightness, by means of a nonmagnetic wall in the airgap between the rotors. The autonomy and the absence of servicing for these couplings also explain their use in high security and pumping devices, as well as in mixing devices in farm-produce or pharmaceutical industries. This article first studies classical permanent magnet coaxial synchronous couplings (Fig. 1) with jointive, identical in shape poles (jointive poles have radial sides in contact); manufactured magnets (called poles of the coupling), alternatively north (whose magnetization is oriented towards the airgap) and south magnetized, are stuck on the inside and outside magnetic rotors.

Section II of this article describes optimization^{2,3} of these structures. Section III deals with new coupling structures that are designed and optimized to solve some problems of screwing devices. It shows that the unscrewing that occurs after the synchronism is broken can be avoided by reshaping the magnets. All the calculations are done with a two-dimensional finite elements program⁴ (FLUX2D). The three-dimensional (3D) phenomena are avoided since all the couplings considered here are 1 m long; they also all have a 2 mm wide airgap and a 50 mm average radius in the airgap. The magnet material is $\text{Sm}_2\text{Co}_{17}$, which is defined with a remanence of 1 T and a magnetic permeability of 1. Its high coercive field (900 kA/m) allows regarding all sorts of magnet shapes with a very low risk of demagnetization.

II. OPTIMIZATION OF CLASSICAL COUPLINGS

The synchronous driving is created by a tangential attraction between opposite magnetized poles, due to the angular deviation between the driving and the driven rotor. The transmitted torque increases with the deviation up to a pull-out value, which is the maximum torque the coupling can transmit. Then, an additional angular deviation breaks the synchronism, and the rotors begin to slip. The knowledge and the control of this pull-out torque allow one to design precise screwing devices, since the screwing stops when this value of torque is reached.

A. Number of poles

At a given distance of a magnet, the level of magnetic induction depends on the outer surface of the magnet (Fig.

2). Moreover, the torque transmitted by a magnetic coupling quadratically depends on the average level of magnetic induction in the airgap. The study of the transmitted torque versus the number of pairs of poles shows that an optimum angular width of the magnets exists for an imposed width of airgap (Fig. 3), since the width of jointive poles is a direct function of the number of poles. This optimum is displaced in Fig. 3, to the left (respectively right) when the airgap is widened (respectively narrowed). For a very large number of poles, the dead zones (parts of magnets where the field lines directly close up on the neighbor pole) cover the whole magnets, and the pull-out torque value tends towards zero.

B. Length of magnets

Two face to face magnets in a coupling are submitted to a primary force due to the magnetic masses⁵ of their airgap surfaces and an opposite secondary force due to the interaction of their posterior face magnetic masses with the airgap face of the other magnet. The increase of their length L (Fig. 1) moves their posterior face away and reduces the strength of the secondary force. The total force is hence increased, and the pull-out torque tends towards an asymptotical value (Fig. 4). The induction level in the magnets, for systems whose length of magnets places them at the bending of the curve on Fig. 4 is the half of the remanent induction level. If the demagnetization characteristic is linear,² this implies that their magnets work at their highest level (point of $-BH_{\text{max}}$), which is of course economically favorable.

FIG. 1. Classical type of a permanent magnet coaxial synchronous coupling.

FIG. 2. Level of induction measured as a function of the distance to the surface, for a wide and a narrow magnet, which have the same length.

C. Conclusion

The goal of the maximum possible pull-out torque necessitates the optimization of both number of poles and length of magnets. This conclusion is subjected to a compromise according to economical criteria, since magnet materials and manufacturing are both expensive. It sometimes appears to be cheaper to add some length of magnets (if the system size allows it), instead of increasing the number of poles.

III. IMPROVEMENT OF COUPLINGS FOR SCREWING DEVICES

The curve linking the transmitted torque to the angular deviation between the rotors is sinusoidal for a classical type of permanent magnet coaxial synchronous couplings (Fig. 5). This symmetrical shape means that after the synchronous screwing—up to the pull-out torque—the lead rotor is submitted to an unscrewing torque that has the same value as the screwing one. The goal of this study is to modify the shape of the poles to reach systems whose torque-deviation curve is as dissymmetrical as possible: negative and positive maximum values of torque and angular ranges for screwing and unscrewing should be as different as possible.

A. Influence of the cyclic ratio

The decrease of the cyclic ratio (ratio of the angular width of the north-magnetized poles on the polar pitch, which is the angular size of two consecutive poles) implies narrower and more angularly spaced out peaks for the curve (Fig. 5). This type of coupling does not have the same angular stiffness depending on the direction of rotation: the slope of the curve is not the same whether it is considered on one side of a peak or on the other side.

FIG. 3. Pull-out torque as a function of the number of pairs of poles.

FIG. 4. Pull-out torque as a function of the length of magnets for a system fitted out with five pairs of poles.

FIG. 5. Transmitted torque versus angular deviation of rotors for two cyclic ratios in the case of a five pairs of poles system.

FIG. 6. Geometry of permanent magnet coupling with inclined plane (a) and inclined plane-plateau (b) south-magnetized poles on inside rotor.

FIG. 7. Comparison of a classical system and a system with inclined planes poles, with five pairs of poles.

FIG. 8. Transmitted torque vs the deviation angle between rotors, for a plateau/pole ratio of 0.33 and a cyclic ratio of 0.25, compared to a classical system (12 pairs of poles).

FIG. 9. Displacement of the middle point of the curve vs the α ratio (12 pairs of poles).

B. Dissymmetrical poles

To have a dissymmetrical behavior of the coupling, the field lines have to be concentrated in the airgap at the positive maximum torque position, but not at the negative maximum torque position. This is why poles that are not invariant by rotation are introduced as poles with inclined planes, for example [Fig. 6(a)]. The whole curve and the angular position of the maximum torque values in the peaks are displaced in the same direction (Fig. 7). The forces are functions of $(1/r^2)$, where r is the distance between magnets. As r is not the same on both sides of the south poles, the resultant force is no longer equal to zero for no deviation. The increase of the slope of the inclined plane emphasizes this phenomenon, and reduces the torque level (the average distance between face to face poles is increased). A plateau made on the south magnets [Fig. 6(b)] allows one to reach higher torque values.

C. Cyclic ratio different from 0.5 and dissymmetrical south-magnetized poles

All the couplings studied at the end of this article are fitted out with 12 pairs of poles. By combining the distance between peaks (due to the decrease of the cyclic ratio, and the displacement of the curve, due to one rotor with south-magnetized poles fitted out with a plateau and an inclined plane) the torque-deviation curves become dissymmetrical (Fig. 8). The relative size of the plateau on the south poles of one rotor, measured by the α ratio of the angular size of the plateau to the angular width of the south poles, has an influence on the dissymmetry of the curve (Fig. 9). This dissymmetry is measured by two parameters: the "Minmax ratio" of the difference between the values of positive and negative maximum torques on the absolute value of the higher maximum (Fig. 10) and the relative displacement of the "middle point" of the curve (M point on Fig. 8). The most interesting

FIG. 11. Minmax ratio and maximum transmitted torque as functions of the length of magnets on the inside rotor (12 pairs of poles).

system with regard to the dissymmetry is thus fitted out with a cyclic ratio of 0.25 and an α ratio of 0.2, for which the unscrewing torque is almost half of the screwing one. This configuration of coupling is considered in the next section. The "perfect case" would be a screwing torque higher than the unscrewing one and a screwing range for rotors angular deviation greater than the unscrewing one, this seems impossible because of the conservation of energy.

D. Influence of the length of asymmetrical magnets

The introduction of dissymmetrical poles implies a loss of torque level. The increase of the magnet length on the dissymmetrical rotor can then be considered. As this increases the imbalance distance between airgap surfaces, the dissymmetry is enhanced (Fig. 11). However, the slope of the inclined plane increases as well, and from a limit value of length, the field lines close up more easily on the neighbor magnet, and do not take part in the airgap induction level. That is why the pull-out torque level does not follow the increase of length (Fig. 11). A compromise will consequently have to be chosen once more, depending on the wanted levels of pull-out torque and dissymmetry.

IV. CONCLUSION

The number of poles and the length of the magnets stuck on the rotors are parameters that allow one to optimize classical permanent magnet coaxial synchronous couplings. It is possible to minimize the volume of magnet for a given torque or to maximize the torque for a given volume. Moreover, new structures of couplings are presented. They are adapted to screwing devices and allow one to avoid the unscrewing which occurs after the end of the synchronous driving and screwing. Original shapes of the magnets give a screwing torque value almost two times higher than the unscrewing one, and therefore solve the problem.

A comparative analysis of permanent magnet-type bearingless synchronous motors for fully magnetically levitated rotors

J. F. Charpentier and G. Lemarquand^{a)}

Université de Bretagne Occidentale, LEMB-IUT de Brest, rue de kergoat, 29287 Brest, France

Radial instability of synchronous motors is important data to design magnetic bearings. Moreover, original motor structures must be proposed to decrease the instability. In this article, four structures with a permanent magnet rotor, six poles, and the same main mechanical dimensions are analyzed and compared. The first concerns a rotor with six tiles of permanent magnets radially magnetized and adhered to an iron core. The second is a rotor with six axial permanent magnets tangentially magnetized and separated by iron pole pieces, where the shaft is amagnetic. The third design proposes a rotor with six contiguous tiles of permanent magnets tangentially magnetized and an amagnetic shaft. In the fourth structure each north pole is made up of two contiguous tiles of permanent magnets tangentially magnetized in opposite direction and each south pole is made up of an iron pole piece. The shaft of this structure is amagnetic. The stator structure and the currents in stator windings produce a six poles flux distribution. A finite element method program is employed to study the forces and the torques. The four structures are designed to provide the same motor performance (torque). The radial instability is modeled by outcentering the rotor. The relationships between the radial force and the type of structure are analyzed. The result is that the third structure is the best solution for fully magnetically levitated rotors. It has a small instability and does not generate any disturbing force whose frequency is the double of the rotation frequency. This structure also has good properties to be used as a radial magnetic bearing. © 1998 American Institute of Physics. [S0021-8979(98)17111-6]

I. INTRODUCTION

Some studies,¹⁻³ showed an interest in bearingless motors. Most of them consider asynchronous machines that fulfill the double function of a motor and a radial bearing. If there are losses in the rotor, the corresponding calories are hardly evacuated from this body that rotates contactless in vacuum. Furthermore some studies⁴ have shown an interest in the synchronous motor compared to an asynchronous motor in term of stability. These are two good reasons to justify the use of permanent magnet synchronous machines. Section III of the article studies and compares four structures of rotors for permanent magnet synchronous machines from a destabilization point of view. Section IV shows that a permanent magnet synchronous machine with three pairs of poles is able to assume the function of a radial bearing. Each phase is constituted by three windings. These windings are not serial or parallel connected, as usually done, but they have separate feedings. The radial forces are obtained via the unbalance of the currents in the windings of a same phase.

II. STRUCTURES PRESENTATION

The aim of this work is to study the influence of the rotor structure of a permanent magnet motor without bearings on the instability and on the radial forces obtained when the windings are unbalanced. Four different structures of six pole three phase motors are presented and evaluated.

A. Choice of the structure of the stator

The structure of the stator is the same for the four different machines. We made the choice of a slotless armature to minimize the influence of the stator parameters in this study. The main dimensions of the stator are:

- (i) armature diameter: 128 mm,
- (ii) coil thickness: 3 mm,
- (iii) mechanic air gap: 2 mm.

The maximum current density in each coil is 6 A/mm². This value corresponds to a suitable temperature rise in the motor under normal conditions of work. The stator structure is described in Fig. 1.

B. Description of the structures of the rotor

Four structures of permanent magnet rotors are considered. They have been designed to deliver the same torque when two phases are fed by the same current. Neodymium iron boron magnets with a remanence of 1 T are used in these structures.

FIG. 1. Stator structure.

^{a)}Electronic mail: lemb@univ-brest.fr

FIG. 2. Rotor structures.

The structures are described in Fig. 2. The first design is a classical design of a PM motor. The magnets are oriented radially and stuck in a cylindrical iron core. In the second structure iron pole pieces sandwich PM segments tangentially magnetized. In the third structure, six opposite tangential permanent magnets are assembled in an ironless rotor. In the fourth structure the south poles are made up of iron pole pieces and the north poles of two opposite tangential permanent magnets.

These structures are studied using a two-dimensional (2D) finite element field calculation code. All the simulation results are given for 1 m long structures.

Figure 3 shows the torque calculated for each motor versus the rotor position when two phases (phases 1 and 3) are fed by the same current. The origin for the rotor position is the position of maximum torque. We can see that the torques developed by these machines are quite similar. Nevertheless the magnet volume is more important in structures 3 and 4 because the magnetic airgap is very large in these types of structures.

III. STUDY OF RADIAL INSTABILITY

A criterion of choice for a motor is not necessarily the performance with regard to the weight, but the fact that it does not destabilize the whole rotating device. When the device is levitated, the stiffness of the bearings has to be higher than the antistiffness of the motor. The presented structures have to be characterized from this point of view.

To study the radial instability of the motors we have simulated the behavior of the structures when the rotor is

FIG. 3. Torque vs angular position of the rotor.

FIG. 4. Forces amplitude versus angular position of the outcentred rotor (outcentering value is 0.8 mm).

outcentered at 0.8 mm. The outcentering is generally due to the unbalance of the rotor. Figure 4 shows the amplitude of the radial forces exercised on the outcentered rotor versus the rotor position for each machine when two phases fed by the same dc current. This radial force is always oriented in the direction of the radial displacement of the rotor. The maximal values of these forces are quite comparable to the values of the tangential forces which contribute to create the torque.

For the third structure, the value of the force created on the outcentered rotor does not vary with the angular position of the rotor. In this structure this radial force is only produced by the influence of the magnets on the iron of the stator.

In structures 1, 2, and 3 the force amplitude varies with the angular position of the rotor. This variation is due to the influence of the windings on the rotor iron. The first two structures present a large variation of the radial forces with the angular position of the rotor. For the fourth structure this variation is less important.

We also note that the values of the forces are more important in the case of structures 1, 2, and 4 than in the case of the third structure.

The radial displacement of the rotor is created by its unbalance and the unbalance has the same angular speed as the rotor. Let us call N the point of the rotor that is the nearest from the stator at every moment. This point is moving with an angular speed ω_n . Let ω_r be the angular velocity of the rotor. When the radial displacement of a magnetically levitated machine corresponds to a direct mode, the movement of the N point is in the same direction as the rotor movement. Thus the angular velocity of the N point with regard to the stator is zero. Point N is always the same point. If this point varies, this will induce movements with a very low frequency: the motor antistiffness is either constant or very slowly variable, which is not a problem dynamically.⁵ On the contrary, when the radial displacement of the machine corresponds to a retrograde mode, the movement of the N point is in the opposite direction as the rotor one. Its movement with regard to the stator has an angular velocity of $\omega_n = -2\omega_r$. As the radial force depends on the rotor position, this implies that the force is modulated with a frequency $2f_r$. As a consequence, this generates an excitation at the frequency $2f_r$, which is a source of the instability of the machines. This explains the presence of second harmonics in the machine's movements and the obligation to damp movements which have this frequency. The more dependent

FIG. 5. Forces amplitude vs angular position of the rotor with unbalanced currents.

on the rotor position the radial force is, the more important the movement at the $2f_r$ frequency is, and the more unstable the machine is. For this reason, structures 1 and 2 are not interesting at all. Structure 4 is acceptable, as the force is modulated slightly by the rotor position. Although not optimum with regard to the volume of magnet, the third structure is dynamically the most interesting because its radial force is independent from the rotor position. Its radial antistiffness (ratio of the radial force over the radial displacement of the rotor) is also the smallest of the four structures and therefore the easier to compensate by the bearings.

IV. STUDY OF RADIAL FORCES OBTAINED WITH UNBALANCED CURRENTS

The rotor is now centered and the currents in the stator are unbalanced to create radial forces. The idea is now to study whether the structures can be also used as magnetic bearings. In Figs. 5 and 6 the force amplitude and orientation are presented versus the rotor position when two phases are fed and unbalanced. One of the three coils of each active phases (1 and 3) is crossed by a 12 A/mm^2 current density

FIG. 6. Forces orientation vs the angular position of the rotor with unbalanced currents.

and the two other coils of these phases by a 3 A/mm^2 current density. Figure 5 shows that structures 1 and 2 create radial forces with a high mean value, but with an important modulation with the rotor position. Furthermore, Fig. 6 shows that the direction of the forces also depends on the rotor position. For the fourth structure, the radial force is very important when the coils are facing the iron of the rotor, and less important when facing the magnets. The modulation is still important. Finally, the third structure creates a force of almost constant amplitude without regard to the angular position of the rotor. The direction of the force varies linearly with the angular position of the rotor. The force is oriented in the direction of the axis of the coil which has the maximum current (50° or 230°) when a pole is facing this axis, and oriented perpendicular to this axis (-40° or 140°) when a pole is facing the current. This means that this configuration is suitable for use as a radial bearing.

V. CONCLUSION

Among the four proposed and studied structures that generate the same torque, some of them are optimized with regard to the volume of magnet that is used to create this torque. But other differences appear when they are studied from two other points of view: that of radial instability and that of the bearing function. Indeed, the destabilizing effect of the motor is an important thing for levitated devices, as the motor should destabilize the rotating system as less as possible. Furthermore, it is interesting to have an actuator that could also fulfill the function of a bearing. It then appears from our study that the third presented structure (although difficult to realize with tangential magnetized magnets, and not optimum with regard to the volume of the magnets) is dynamically the most interesting one. Indeed, it has very good characteristics, when considering its radial instability, especially with regard to the creation of a disturbing force at a frequency that is double the rotation frequency. This structure is also easy to control as a radial magnetic bearing.

Spin reorientation in (Pr,RE)–(Co,TM)–B magnets (RE=Tb, TM=Fe,Cr,Mn)

D. H. Kim and G. Hadjipanayis

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716-2570

Small substitutions of Pr with Tb and Co with Fe, Cr, Mn were used to increase the spin reorientation temperature of the $\text{Pr}_2\text{Co}_{14}\text{B}$ compound which is around 395 °C. Spin reorientation temperatures were obtained by measuring magnetization vs temperature curves at temperatures up to 750 °C. Several ribbons with high spin reorientation temperature were fabricated by melt-spinning and they were annealed in the temperature at 600–700 °C to obtain the optimum coercivity. Our results show that spin reorientation temperature is sharply increased with Fe substitution and reaches a maximum (575 °C) in the sample with 25% Fe substituted for Co. Small amounts of Tb, Cr, and Mn are effective in increasing the spin reorientation temperature. The optimum coercivities of ribbons are in the range of 7–10.5 kOe and ribbons with high spin reorientation temperature show an improved temperature dependence of coercivity. © 1998 American Institute of Physics. [S0021-8979(98)36311-2]

I. INTRODUCTION

$\text{Nd}_2\text{Co}_{14}\text{B}$ and $\text{Pr}_2\text{Co}_{14}\text{B}$ magnet alloys exhibit high Curie temperatures, which make them the possibility for high temperature application.^{1–3} Among them, the anisotropy field of $\text{Nd}_2\text{Co}_{14}\text{B}$ is significantly lower and makes this Co-substituted alloy a poor candidate to become permanent magnet. In the case of $\text{Pr}_2\text{Co}_{14}\text{B}$, an opposite behavior is observed with the anisotropy field of $\text{Pr}_2\text{Co}_{14}\text{B}$ being much higher than that of $\text{Pr}_2\text{Fe}_{14}\text{B}$. Several studies have reported that high coercivities with value up to 25 kOe in sintered magnets⁴ and melt-spun $\text{Pr}_2\text{Co}_{14}\text{B}$ ribbons could be obtained.^{5,6} However, the $\text{Pr}_2\text{Co}_{14}\text{B}$ magnet has a spin reorientation temperature at around 395 °C⁷ where its anisotropy is changed from uniaxial to planar, this puts an upper temperature limit on the application of these magnets.

In this study we tried to prepare Pr(Tb)–Co(Fe,Cr,Mn)–B-based magnets with higher spin reorientation temperature. As is well known, no spin reorientation is observed in $\text{Pr}_2\text{Fe}_{14}\text{B}$ and the spin reorientation temperature of $\text{Tb}_2\text{Co}_{14}\text{B}$ is much higher than that of $\text{Pr}_2\text{Co}_{14}\text{B}$.

II. EXPERIMENT

All the alloys with $(\text{Pr,RE})_{13}(\text{Co,TM})_{80}\text{B}_7$ (RE=Tb, TM=Fe, Cr, Mn) were prepared by arc-melting, followed by homogenization at 1000 °C for 24 h under Ar atmosphere. Spin reorientation temperature was obtained by measuring magnetization vs temperature curves at temperatures up to 750 °C. Several ribbons with high spin reorientation temperature were fabricated by melt-spinning at a wheel speed of 50 m/s. The as-spun ribbons were confirmed to be almost amorphous within the resolution of x-ray diffraction experiment. The ribbons were studied using differential scanning calorimetry (DSC) for the identification of possible phase transformation. The coercivity of samples was optimized through annealing at the temperature range of 600–700 °C for 2.5–40 min. Magnetic properties were measured by a vibrating sample magnetometer (VSM) with a maximum field of 20 kOe and the temperature dependence of coercivity was measured up to 450 °C.

III. RESULTS AND DISCUSSION

The temperature dependence of magnetization curves for $\text{Pr}_{13}(\text{Co}_{1-x}\text{Fe}_x)_{80}\text{B}_7$ ($x=0.1, 0.25, 0.6$) alloys are shown in Fig. 1. The curves were measured in a low applied magnetic field of 200 Oe to show clearly the effects of magnetic transitions. As one can see, the magnetization increases as the temperature increases due to the decline of magnetocrystalline anisotropy field with temperature, and all curves exhibit an unusual curvature at the temperature where its anisotropy is changed from uniaxial to planar. The spin reorientation temperature is determined from the inflection point of this curve. Using the same method, the spin reorientation temperatures for $\text{Pr}_{13}(\text{Co}_{1-x}\text{Fe}_x)_{80}\text{B}_7$ ($0 \leq x \leq 0.6$) were obtained as shown in Fig. 2. It is found that spin reorientation temperature is sharply increased with Fe substitution because there is no spin reorientation in the $\text{Pr}_2\text{Fe}_{14}\text{B}$, and reaches a maximum (575 °C) in the sample with 25% Fe substitution for Co. But for higher Fe substitution, the spin reorientation temperature is dropped down to around 300 °C. In the $\text{Pr}_2(\text{Fe,Co})_{14}\text{B}$ system, the magnetocrystalline anisotropy is strongly dependent on the Fe content and shows a minimum at the composition with 25% Fe content.³ Therefore, at this composition, a confusion of magnetocrystalline anisotropy may be existed and cause a drop of the spin reorientation temperature, which originates from the competition between the 3d and 4f sublattice anisotropy.³ On the other hand, the Curie temperature of the sample is continuously decreased as the Fe content increases.

Figure 3 shows the temperature dependence of magnetization curves for $\text{Pr}_{13}(\text{Co}_{0.4}\text{Fe}_{0.6})_{79}\text{M}_1\text{B}_7$ ($\text{M}=\text{Cr, Mn}$). The results indicate that samples with a small amount of Cr and Mn do not show spin reorientation phenomena up to the Curie temperature. In the case of $(\text{Pr}_{1-z}\text{Tb}_z)_{13}(\text{Co}_{0.4}\text{Fe}_{0.6})_{80}\text{B}_7$ ($z=0.2, 0.5$), as shown in Fig. 4, Tb substitution is effective in increasing both the spin reorientation temperature, with 1 °C/1% Tb ratio, and the Curie temperature.

X-ray diffraction showed that all the as-spun ribbons were almost amorphous in structure. Calorimetric DSC studies showed that all the samples have an exothermic peak at

around 550 °C where the amorphous phase transforms into the 2:14:1 phase.

Figure 5 shows the coercivity change as a function of aging time at 600–700 °C for $\text{Pr}_{13}(\text{Co}_{0.5}\text{Fe}_{0.5})_{80}\text{B}_7$ ribbons. To develop a high coercivity, an annealing temperature over

FIG. 4. Temperature dependence of magnetization for (a) $(\text{Pr}_{0.8}\text{Tb}_{0.2})_{13}(\text{Co}_{0.4}\text{Fe}_{0.6})_{80}\text{B}_7$ and (b) $(\text{Pr}_{0.5}\text{Tb}_{0.5})_{13}(\text{Co}_{0.4}\text{Fe}_{0.6})_{80}\text{B}_7$.

FIG. 5. Coercivity change as a function of aging time at temperatures in the range of 600–700 °C for $\text{Pr}_{13}(\text{Co}_{0.5}\text{Fe}_{0.5})_{80}\text{B}_7$.

600 °C is required and the optimum coercivity is 10.5 kOe after annealing at 650 °C for 2.5 min. The other samples show a similar trend and optimum coercivities are in the range of 7–10.5 kOe as listed in Table I. The lowest coercivity is obtained in the sample with 25% Fe substitution where the maximum spin reorientation temperature was obtained. This is because the magnetocrystalline anisotropy is a minimum at the composition with maximum spin reorientation temperature. In the Cr and Mn cases, the substitutions were not effective to improve the coercivity.

Figure 6 shows the temperature dependence of coercivity for $\text{Pr}_{13}(\text{Co}_{1-x}\text{Fe}_x)_{80}\text{B}_7$ ($x=0.2, 0.25$, and 0.5) ribbons having different spin reorientation temperature. Samples with $x=0.2$ and 0.25 which have higher spin reorientation temperature (480 and 575 °C, respectively) show a low coercivity at room temperature because of their lower magnetocrystalline anisotropy field. However, as the temperature increases the decline of coercivity is smaller than the other sample with $x=0.5$ which has a lower spin reorientation temperature (395 °C). In order to be shown this tendency more clearly, the ratio of coercivity decrease (H_c/H_c at room temperature) as a function of temperature is shown in Fig. 6(b).

TABLE I. Optimum coercivities in $\text{Pr}_{13}(\text{Co,TM})_{80}\text{B}_7$ ribbons.

Sample	T_{sp} (°C)	H_c (kOe)	Annealing condition
$\text{Pr}_{13}(\text{Co}_{0.8}\text{Fe}_{0.2})_{80}\text{B}_7$	480	7.0	650 °C, 5 min
$\text{Pr}_{13}(\text{Co}_{0.75}\text{Fe}_{0.25})_{80}\text{B}_7$	575	7.4	650 °C, 5 min
$\text{Pr}_{13}(\text{Co}_{0.5}\text{Fe}_{0.5})_{80}\text{B}_7$	395	10.5	650 °C, 2.5 min
$\text{Pr}_{13}(\text{Co}_{0.4}\text{Fe}_{0.6})_{79}\text{Cr}_1\text{B}_7$	-	9.1	650 °C, 5 min

FIG. 6. Temperature dependence of coercivity for $\text{Pr}_{13}(\text{Co}_{1-x}\text{Fe}_x)_{80}\text{B}_7$ ($x=0.2, 0.25$, and 0.5) having different spin reorientation temperature.

IV. CONCLUSIONS

High spin reorientation temperatures of 575 °C have been obtained in $\text{Pr}_{13}(\text{Co}_{0.75}\text{Fe}_{0.25})_{80}\text{B}_7$ with relatively small decline of Curie temperature. Samples with a small amount of Cr and Mn do not show spin reorientation phenomena up to their Curie temperature, which is found to decrease with substitution. Tb substitution is effective in increasing both the spin reorientation temperature, with 1 °C/1% Tb ratio, and the Curie temperature. Samples with higher spin reorientation temperature show an improved temperature dependence of coercivity.

Injection-molded, oriented hybrid magnets consisting of mixtures of $\text{BaO} \cdot 6\text{Fe}_2\text{O}_3$ and MQP-Q (exchange-coupled $\text{Nd}_2\text{Fe}_{14}\text{B} + \alpha\text{-Fe}$) are compared to bonded magnets made only from ferrite or MQP-Q. The magnetic fractions of the hybrid magnets consist of 80, 60, or 40 wt % ferrite blended with 20, 40, or 60 wt % MQP-Q. The microstructure was investigated by x-ray diffraction, scanning electron microscopy, atomic force microscopy, and magnetic force microscopy. Atomic and magnetic force microscopy images indicated differences between the physical and magnetic microstructures. Magnetic interactions were studied via isothermal remanence (IRM) and dc-demagnetization (DCD) remanence curves and Henkel plots. In contrast to what is observed in exchange spring magnets, the IRM and DCD susceptibilities of all magnets present peaks of nearly the same width, centered at roughly the same value of the magnetic field, consistent with weak dipolar interactions between magnetic particles. The IRM susceptibilities show structure associated with magnetic inhomogeneities in the samples. © 1998 American Institute of Physics. [S0021-8979(98)17211-0]

Bonded magnets constitute the fastest growing segment of the permanent magnet market.^{1,2} These materials are produced by encapsulating a magnetic powder in a resin or polymer and then compacting or molding the material to the final part shape. The commercially important bonded magnets are based primarily upon ferrite or NdFeB . However, low-neodymium, exchange-coupled alloys are also interesting for bonded magnets because of their good corrosion resistance and low saturation fields. The Magnequench alloy MQP-Q ($\text{Nd}_2\text{Fe}_{14}\text{B} + \alpha\text{-Fe}$) has recently been used with barium ferrite to produce hybrid magnets with interesting coercive properties.² For a bonded magnet whose magnetic fraction consists of 20 wt % MQP-Q and 80 wt % ferrite, the reversible temperature coefficient of coercivity is approximately zero around and above room temperature. Furthermore, at 100 °C, the coercive field H_c of the hybrid is larger than that of either the bonded ferrite or the bonded MQP-Q. Enhanced hysteresis characteristics due to anisotropic dipole interactions have been observed³ in composite mixtures $\text{Sm}_2\text{Co}_{17}/\text{Sm}_2\text{Fe}_{17}\text{N}_3$ and $\text{Sm}_2\text{Co}_{17}/\text{Fe}$.

In this article, we investigate magnetic interactions in several hybrid magnets and present data on their magnetic and structural properties. The bonded magnets present an ideal opportunity to study systems in which dipole interactions should be the predominant form of interaction between particles.

Five commercial bonded magnet compositions were considered in this work. Three anisotropic hybrid magnets, produced by injection molding, had magnetic fractions consisting of 80, 60, or 40 wt % Ba ferrite blended with 20, 40, or 60 wt % of MQP-Q melt-spun ribbons and a binder of

Nylon 12. These have been designated as samples 2401, 2402, and 2403, respectively. An anisotropic magnet consisting only of Ba ferrite is designated as 1060, while an isotropic magnet whose magnetic fraction is MQP-Q is identified as 2203. For the latter two magnets, polyamide was used as a binder. The saturating field requirements as well as the temperature dependence of the coercivity for these magnets have been published previously.² For all magnets, we were able to reproduce the catalog density by assuming the volume fraction of the magnetic material to be 60%.

The alignment of these magnets was characterized with a Philips MDP 1880 powder diffractometer using $\text{Cu } K\alpha$ radiation. The microstructure was examined with an optical microscope as well as with a Leica Cambridge F440 scanning electron microscope (SEM). Magnetization M measurements between 4.2 and 300 K were made with a vibrating sample magnetometer mounted in a 9 T superconducting coil, while measurements above 300 K were made in a furnace mounted on a 2 T electromagnet. In all cases, M versus H was corrected using an appropriate demagnetization factor.

Images were also obtained using a Digital Instruments D3000 scanning probe microscope. The device allows simultaneous collection of topography data, by Tapping ModeTM atomic force microscopy (AFM), and magnetic stray field data, by LiftModeTM magnetic force microscopy (MFM).⁴ The topographical information from each raster line is used to maintain a constant height above the sample surface during collection of the magnetic information to minimize the effect which topological features have on the stray field distribution. In the topological images, light areas are higher than the average and dark areas are lower than the average.

^{a)}Electronic mail: fmissell@macbeth.if.usp.br

FIG. 1. SEM image of sample 2401 showing inhomogeneous distribution of MQP-Q ribbons.

In the magnetic images, light areas correspond to tip-sample interactions producing a negative force gradient, while positive gradients correspond to dark areas.⁴

In the hybrid magnets, the Ba ferrite grains present a high degree of alignment as can be verified by x-ray diffractograms in which the (00 k) peaks of this phase are prominent. Optical metallography and SEM observations show the ribbons of MQP-Q to be randomly dispersed in the ferrite-Nylon 12 matrix. In Fig. 1, a low magnification SEM image of sample 2401 is presented where the random orientation of the MQP-Q ribbons can be seen. A useful way to quantify the degree of alignment of these samples is in terms of the ratio M_r/M_s , where M_r is the measured remanence and M_s is the saturation magnetization, obtained by extrapolating high-field M values to infinite fields using $M=M_s(1-a/H)$. Values of M_r/M_s are presented in Table I. This ratio is seen to decrease as the ferrite fraction of the magnet decreases. Values of $M_r/M_s=0.8-0.9$ are commonly encountered in aligned sintered magnets, while $M_r/M_s=0.5$ is the value expected for noninteracting single-domain particles.

A group of Ba ferrite grains in an unmagnetized sample of 2401 can be clearly seen in Fig. 2(a), which was obtained by AFM. Note the presence of a large ferrite grain in the center of the figure. The magnetic stray fields for the same region of the sample, obtained by MFM, are shown in Fig. 2(b). The magnetic stray fields associated with the large ferrite grain in the center of the figure are very nonuniform over the grain, indicating the presence of two domains in this grain. Furthermore, the stray fields of several small neighboring grains have the same orientation as one of the do-

FIG. 2. (a) AFM image of the $5\text{ }\mu\text{m}\times 5\text{ }\mu\text{m}$ region of Ba ferrite in sample 2401. (b) MFM image of the same $5\text{ }\mu\text{m}\times 5\text{ }\mu\text{m}$ region showing stray magnetic fields present in the sample. Note that the magnetic domain structure does not coincide with the grain structure.

main in the large central grain. In general, we can see that the stray field distribution does not coincide with the grain structure of the sample. It is known that magnetic interactions between neighboring grains can lead to collective phenomena, known as interaction domains. The details of inter-grain interactions will depend upon exchange, anisotropy, magnetic moment, grain size, and grain misorientation, all of which will affect the stray fields. Interaction domains have been observed in many kinds of magnets, including exchange-coupled nanostructured rare-earth magnets.⁵ In the present case, the existence of interaction domains is evidence for locally inhomogeneous magnetization states in the hybrid magnets.

A magnetic evaluation of magnetostatic interactions was made using the so-called IRM and DCD remanence curves and Henkel plots. The isothermal remanence (IRM) curve $M_r(H)$ started from an ac-demagnetized state, with the remanent magnetization being measured as a function of increasing positive applied field until positive saturation was obtained. The dc-demagnetization (DCD) curve $M_d(H)$ was measured from a positive saturation condition, with the remanence measured as a function of increasing negative field, until negative saturation was reached. For any system of single-domain noninteracting particles, Wohlfarth showed that $M_d(H)=M_r(\infty)-2M_r(H)$.

In Fig. 3, we show the IRM and DCD susceptibilities, $\chi_r=dM_r/dH$ and $\chi_d=dM_d/dH$, for the five magnets studied. For noninteracting systems, the two curves should be of the same width, should have maxima at the same values of

FIG. 3. IRM and DCD susceptibilities of the bonded magnets studied. For magnet 2401, the two IRM curves are for different samples and show different structure.

the magnetic field, and the amplitudes should differ by a factor of 2, as can be seen by differentiating the Wohlfarth relation. Values of the widths and centers of the IRM (Δ_r, H_r) and DCD (Δ_d, H_d) curves are given in Table I. It is most remarkable that these predictions are roughly obeyed for the five magnets studied, even though four of them contain varying amounts of exchange-coupled MQP-Q. A recent study⁶ of several exchange-coupled NdFeB alloys showed that the amplitude of χ_d was up to 50 times greater than that of χ_r , while the width of the former was about ten times less than the latter. On the other hand, CoNiCr thin films⁷ approached the ideal behavior for large values of the Cr underlayer thickness, consistent with a reduction in exchange coupling between grains with increasing Cr underlayer.

In Fig. 3, two χ_r curves are shown for magnet 2401, corresponding to different samples. Each curve presents some structure, not unlike, but smaller than that reported in Ref. 6. However, the structure observed on the two curves corresponding to sample 2401 in Fig. 3 is different from curve to curve. Since our samples clearly present inhomogeneities (see Fig. 1) in the distribution and orientation of the MQP-Q ribbons, we believe this to be the probable cause of the structure observed in χ_r .

Finally, in Fig. 4 we present Henkel plots [$m_d = M_d(H)/M_r(\infty)$ versus $m_r = M_r(H)/M_r(\infty)$] for the five magnets studied in this paper. The diagonal line corresponds to the Wohlfarth line mentioned above. Points above this line correspond to magnetizing interactions, while points below this line are indicative of demagnetizing interactions. In Fig. 4 there is a clear progression in the behavior of the data as the fraction of MQP-Q is increased (fraction of ferrite is decreased). Sample 1060 shows strong magnetizing interactions at low fields. Data for sample 2401 present an s-shaped behavior, which has been seen frequently in exchange-coupled magnets.⁸ This s-shaped curve has been discussed via the Preisach model in terms of a competition between

FIG. 4. Henkel plots for all samples, in which the reduced DCD remanence is given as a function of the reduced IRM remanence.

mean-field effects and random interactions.⁸ Finally, for sample 2203, whose magnetic fraction is only MQP-Q, all points are in the demagnetizing region of the Henkel plot.

Henkel plots can be discussed in terms of the Preisach model,⁹ where one can invoke random interactions and magnetizing or demagnetizing mean-field interactions to explain behavior such as that seen in Fig. 4. Here, we will limit our comments to a comparison with comparable fully dense magnets. For example, the Henkel plot of a fully dense Ba ferrite magnet shows much stronger magnetizing interactions, with nearly all of the data points lying above the Wohlfarth line. For the bonded magnet (1060) shown here, the magnetizing mean-field contributions seem to have been reduced considerably. Similarly, exchange-coupled magnets show an s-shaped Henkel plot, which has been discussed using the Preisach model in terms of a competition between mean-field effects and random interactions.⁸ In the present case, sample 2203 appears to have greatly reduced or negative mean-field interactions. Thus, the effect of the binder may be to reduce the mean-field effects in these bonded magnets.

Mechanical strength of the solid-HDDR treated Nd-Fe-B-type materials

H. W. Kwon^{a)} and S. J. Kang

Department of Materials Science and Engineering, The Pukyong National University, Nam-Gu, Pusan, South Korea 608-737

The hydrogenation, disproportionation, desorption, recombination (HDDR) is known as a unique process through which a noncoercive cast Nd-Fe-B-type material can be easily converted into a coercive one. Although the conventional HDDR process generally leads to a powderlike material, a solid-HDDR material can be realized if the HDDR process is properly modified (solid-HDDR). In the present study, the change of mechanical strength (compressive strength) of the Nd-Fe-B-type material during the solid-HDDR has been investigated using a sintered magnet with composition $\text{Nd}_{13.8}\text{Dy}_{0.7}\text{Fe}_{78.25}\text{Si}_{0.15}\text{Mn}_{0.6}\text{B}_{6.5}$. It has been found that the low strength of the hydrided material was improved by the subsequent disproportionation. The restoration of the strength was explained by the eutectoidlike disproportionation structure containing fine neodymium hydride rod embedded in tough iron matrix. The high strength of disproportionated material was reduced radically in an earlier stage of recombination, and this was explained by the reduction of the disproportionated phase. The reduced strength was, however, recovered by further recombination, and this was explained by the fact that as the recombination continues the recombined grains become continuous and adhere together. The optimally HDDR processed material has a comparable or even higher strength with respect to the initial sintered material prior to the solid-HDDR. The present study suggested that the mechanical strength of Nd-Fe-B-type material could be retained even after the solid-HDDR. © 1998 American Institute of Physics. [S0021-8979(98)17311-5]

I. INTRODUCTION

The hydrogenation, disproportionation, desorption, recombination (HDDR) is known as a unique process through which a noncoercive cast Nd-Fe-B-type material can be easily converted into a coercive one, and the HDDR process generally leads to a powderlike material.¹⁻⁴ It has been reported, however, that material in a solid form can be obtained by the HDDR process if it is properly modified (solid-HDDR).^{5,6} Noncoercive Nd-Fe-B-type cast ingot material can, therefore, be converted into a magnet with high coercivity in solid form using the solid-HDDR process, and a successful attempt has been reported by another group.⁵ In order that the solid-HDDR treated material can be utilized as a magnet, the material has to exhibit not only a high coercivity but also a sufficient mechanical strength. It is, therefore, of great interest to well understand the change of mechanical strength of the Nd-Fe-B-type material during the solid-HDDR.

II. EXPERIMENT

In order to assess correctly the mechanical strength of HDDR treated material, it is important to use a compositionally and structurally homogeneous material. Since an ordinary Nd-Fe-B-type ingot material has a variety of inhomogeneity and structural flaws, the cast ingot material is considered to be unsuitable for assessing the change of mechanical strength during the HDDR. In the present study, therefore, a sintered magnet rather than a cast ingot material was used because the sintered magnet could be considered to be more homogeneous in terms of composition and structure.

The magnet used was anisotropic with a chemical composition of $\text{Nd}_{13.8}\text{Dy}_{0.7}\text{Fe}_{78.25}\text{Si}_{0.15}\text{Mn}_{0.6}\text{B}_{6.5}$. A disk-shaped (13 mm ϕ , 3 mm thick) sample was subjected to a solid-HDDR process. The sample was heated under vacuum up to around 650 °C, at which hydrogen gas was introduced. After introducing the hydrogen gas, the sample was heated rapidly (50 °C/min) toward the disproportionation temperature. The sample disproportionated for a given period was subsequently subjected to the desorption and recombination treatment under vacuum. The samples at each step were rapidly cooled down to room temperature to stop further process and then removed from the HDDR reactor. The compressive strength of the materials under various conditions was measured using a universal testing machine. The dimensions of the specimen used for the measurement of the compressive strength were 5×5×3 mm³. Compression was performed along the direction parallel to the aligning direction of the anisotropic sintered magnet with a strain rate of 2.7×10⁻³/s.

III. RESULTS AND DISCUSSION

The hydrogenated sample showed very friable character and no appreciable strength was measured. The low strength of the hydrided material was enhanced by disproportionation. Variation of the compressive strength as a function of the disproportionation temperature for the samples disproportionated for 2 h at each temperature was examined and the result is shown in Fig. 1. It appears that the compressive strength of the sample disproportionated at low temperature (650 °C) appears to be very low compared to the initial strength (85 kgf/mm²) prior to the HDDR, and it increases with increasing the disproportionation temperature up to 800 °C, above which it levels off. Of particular interest is

^{a)}Electronic mail: hwkwon@dolphin.pknu.ac.kr

FIG. 1. Variation of the compressive strength as a function of disproportionation temperature for the hydrogenated magnet.

FIG. 3. Variation of the compressive strength as a function of recombination temperature for the fully disproportionated material.

that the compressive strength of the fully disproportionated material has been found, unexpectedly, to be higher than that of the initial sintered magnet before HDDR. The low strength of the sample disproportionated at the lower temperatures may be explained by the presence of a significant amount of brittle hydride phase which has not been disproportionated. As the disproportionation temperature increases, more disproportionation reaction may proceed for the given period and the remaining hydride may be lessened. It has been reported^{6,7} that the disproportionation of the $\text{Nd}_2\text{Fe}_{14}\text{BH}_x$ and the $\text{NdFe}_4\text{B}_4\text{H}_x$ phases leads to a particular eutectoidlike microstructure consisting of fine neodymium hydride rods embedded in a tough iron matrix. The disproportionated phases are, therefore, expected to have a considerable mechanical strength because of the particular structure containing plenty of tough iron. The gradual increase in the compressive strength with increasing the temperature may, thus, probably be explained by the gradual increase in the amount of disproportionated phases.

Variation of the compressive strength as a function of disproportionation time for the samples at fixed temperature was examined and the results are shown in Fig. 2. It is apparent that the compressive strength at each temperature in-

creases as the disproportionation time increases and then levels off. For the sample disproportionated at low temperature, the strength has not reached the peak value within the period used in the present study and still increases. The gradual increase in the compressive strength is due, needless to say, to the increase in the amount of the disproportionated phase as the time goes on.

It should be interesting to know whether the high compressive strength observed from the fully disproportionated sample can be maintained when it is subjected to a subsequent recombination. The fully disproportionated sample (disproportionated at 800 °C for 2 h) was subjected to recombination under vacuum at various temperatures for 1 h. The variation of the strength as a function of the recombination temperature is shown in Fig. 3. It appears that the compressive strength of the samples recombined at temperatures lower than 800 °C still shows relatively high strength over 70 kgf/mm². On the other hand, the samples recombined at higher temperature above 850 °C have significantly low strength around 30 kgf/mm². The high strength observed in the samples recombined at lower temperature may be due to the presence of a significant amount of the tough disproportion-

FIG. 2. Variations of the compressive strength as a function of disproportionation time at various temperatures for the hydrogenated magnet.

FIG. 4. Variation of the compressive strength as a function of recombination time at 900 °C for the fully disproportionated material.

FIG. 5. X-ray diffraction spectrum of the materials recombined at 900 °C for different periods.

tionated phases which have not been recombined. As the temperature increases the recombination reaction may proceed more rapidly, and a greater amount of the recombined grains may be formed. The lower strength of the samples recombined at higher temperature may, therefore, be attributed to the reduction of the tough disproportionated phases. It should be noted that this sample may certainly have a significant amount of recombined phase. The recombined grains may, however, be distributed discontinuously throughout the sample and no significant adhesion between the grains may have been achieved. This may possibly explain the low strength observed from the samples recombined at higher temperatures.

It should be interesting to see whether the low strength of the sample recombined at higher temperatures observed in the previous result can be enhanced by a further recombination. The change of compressive strength with the recombination time at 900 °C was examined and the result is shown in Fig. 4. It is apparent that the strength increases as the recombination time increases, and then levels off after 4 h. As discussed earlier, the low strength observed from the samples recombined for shorter periods may be attributed to the reduction of tough disproportionated phases (see Fig. 5). As the time increases the recombination may continue, thus resulting in further reduction of the disproportionated phases and leading to a greater formation of the recombined $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase (see Fig. 5). It should be emphasized here that the recombined grains may begin to distribute more continuously throughout the sample and adhere together. The strength of the sample may, therefore, be recovered, and this explains the gradual increase in the strength with recombina-

tion time. The saturation of the strength enhancement observed from the samples recombined longer than 4 h may be due to the completion of the recombination. It is worth noting that, as can be seen in the Fig. 4, the fully recombined sample has a comparable or even higher strength with respect to the initial sintered material prior to the solid HDDR. The present study thus indicates clearly that a properly controlled solid-HDDR process can lead to a material in a solid form with a sufficient mechanical strength. It should be noted that the development of magnetic properties with the solid-HDDR step has not been studied in the present work. Further work is presently under way to investigate the magnetic properties using a cast ingot material.

IV. CONCLUSIONS

The compressive strength of the solid-HDDR material was measured for the sintered magnet under various HDDR conditions, and it has been found that the low strength of the hydrided material was improved by the subsequent disproportionation. The restoration of the strength was explained by the eutectoidlike disproportionation structure containing fine neodymium hydride rod embedded in tough iron matrix. The high strength of disproportionated material was reduced radically in an earlier stage of recombination, and this was explained by the reduction of the disproportionated phase. The reduced strength was, however, recovered by further recombination, and this was explained by the fact that, as the recombination continues, the recombined grains become continuous and adhere together. The optimally HDDR processed material has a comparable or even higher strength with respect to the initial sintered material prior to the solid-HDDR. The present study suggested that the mechanical strength of Nd-Fe-B-type material could be retained even after the solid-HDDR.

Thermal expansion of compounds $R_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ ($R=\text{Y}$ and Gd ; $n=1, 2, 3$, and ∞)

H. Ido, Y. Suzuki, and T. Suzuki

Department of Applied Physics, Tohoku Gakuin University, Tagajo 985, Japan

Thermal expansions of the lattice parameters a and c of the system in the title have been measured by x-ray diffraction technique to investigate the nature of magnetic interactions as well as chemical bond in these systems. Our data reveals that a spontaneous magnetostriction caused by the Co-Co intrasublattice interaction in YCo_4B ($n=1$) occurs in the c plane unlike YCo_5 whose magnetostriction occurs only along the c axis. It is also found that the positive spontaneous magnetostriction of GdCo_4B in the c plane can be divided into three contributions due to the Co-Co, Co-Gd, and Gd-Gd interactions in the crystal. Thermal expansion coefficients in the c plane in the paramagnetic temperature region strongly decrease with increasing n in the Gd system. This implies a significant covalent bonding in the R-B layer in the present compounds. These results are discussed on the basis of the results of energy band calculation together with the previous magnetic data. © 1998 American Institute of Physics. [S0021-8979(98)36411-7]

I. INTRODUCTION

The compound systems expressed by the general formula $R_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ (R : rare earth; $n=0, 1, 2, 3$, and ∞) are known to have interesting crystallographic regularity as shown in Fig. 1.^{1,2} Recently energy band calculations were performed³ for YCo_4B and YCo_3B_2 compounds, and the magnetic moment of the Co atoms at the different crystallographic sites (see Fig. 1) were also evaluated and found to be in qualitative agreement with experimental data. These results reflect the crystallographic regularity. In this work, thermal expansions along the a and c axis were measured by x-ray diffraction for the systems in the title to obtain spontaneous magnetostrictions in the ferrimagnetic ($R=\text{Gd}$) or ferromagnetic ($R=\text{Y}$) temperature region and thermal expansion coefficients in the paramagnetic temperature region. The former provides an information about the nature of exchange interactions and the latter the nature of chemical bonds in the present compound systems. Experimental data are discussed by taking into account the crystallographic regularity shown in Fig. 1.

II. EXPERIMENTAL METHOD AND RESULTS

To determine the temperature variations of the lattice parameters a and c , x-ray ($\text{CuK}\alpha$) diffraction angles of (200)

and some (00 l) lines for powdered samples were measured as function of temperature. The results are shown in Figs. 2 to 6.

Curie temperatures determined by magnetization measurements are also shown by arrows in Figs. 2 to 6. Spin reorientation from axial to planar anisotropy with decreasing temperature was found only for YCo_4B ² at around T_{SR} shown in Fig. 3. A small anomaly was found for the a axis near T_{SR} , which was also found in the work by Hong *et al.*⁴ From the data shown in Figs. 2 to 6, we obtained the following main results; (1) the spontaneous magnetostriction occurs only for the a axis, (2) the spontaneous magnetostriction of the Gd system is larger than that of the Y system (see Figs. 2 and 3), which seems to decrease with increasing n because there are no clear anomaly at the Curie temperatures (see Fig. 5), and (3) a linear thermal expansion coefficients α_a ($=1/ada/dT$) and α_c ($=1/cdc/dT$) in the paramagnetic temperature region showing a clear contrast, namely, α_a and α_c decreases and increases significantly with increasing n , respectively, as illustrated in Fig. 7. The above results (1) and (2) correlate with the nature of magnetic interactions in the present compound systems, and the result (3) shows the

FIG. 1. Crystal structure of $R_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ compound system. The crystallographic units A and B, and three different Co atoms, Co(0), Co(1), and Co(2) are explained and used in the text.

nature of the chemical bond in the present systems having the crystallographic regularity shown in Fig. 1.

III. DISCUSSION OF EXPERIMENTAL RESULTS

A. Thermal expansion in the paramagnetic temperature region

It is convenient to discuss first the results (3) mentioned above. It is very interesting that α_a decreases significantly as n (or B content) increases and reaches $0.87 \times 10^{-6} \text{ deg}^{-1}$ at $n = \infty$ (or GdCo_3B_2). This value is even smaller than the linear thermal expansion coefficient of diamond⁵ ($= 1.0 \times 10^{-6} \text{ deg}^{-1}$), which implies that a strong covalent bond is formed in the R-B layer. The n -dependence of α_a can be explained by the fact that the number of R-B layer in the crystals of $\text{R}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ increase as n increases as seen in Fig. 1. It is also noted² that the a axis of $\text{R}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ expands significantly as n changes from $n=0$, where there is no R-B layer, to $n=1$ though the atomic radius of B is smaller than that of the Co atom. This fact also may suggest the existence of the strong covalent bond in the R-B layer mentioned above.

Before discussing the n -dependence of α_c , we will discuss the magnetic moments of the Co atoms in $\text{R}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$. As seen in Fig. 1, there are three kinds of Co atoms expressed by Co(0), Co(1), and Co(2) which oc-

FIG. 4. Temperature dependence of c axis for GdCo_4B and YCo_4B . No spontaneous magnetostriction is observed.

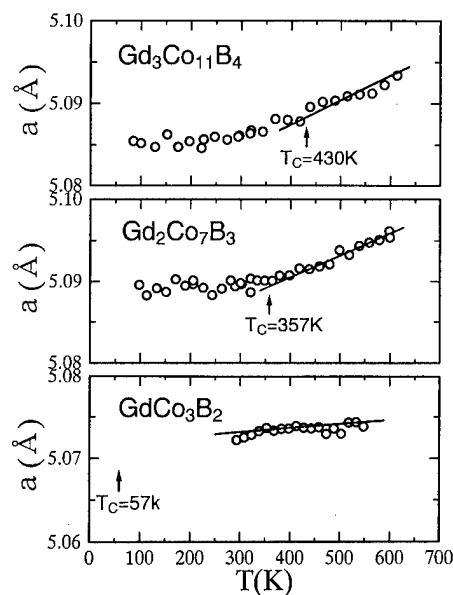

FIG. 5. Temperature dependence of a axis for $\text{Gd}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ with $n = 2, 3$, and ∞ .

cupy the different crystallographic sites. Co(N), where N is 0, 1 or 2, means the Co atom having N -neighboring R-B layer(s). If the magnetic moment of Co(N) is expressed by $\mu_{\text{Co}}(N)$ and is assumed to be constant throughout the $\text{Y}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ system, the averaged Co moment $\mu_{\text{Co}}(n)$ is expressed by the following equation for n :

$$\mu_{\text{Co}}(n) = (2\mu_{\text{Co}}(0) + 6\mu_{\text{Co}}(1) + 3(n-1)\mu_{\text{Co}}(2)) / (3n+5). \quad (1)$$

YCo_3B_2 which includes only Co(2) was found to be Pauli paramagnetic with a susceptibility of $\chi = 1.9 \times 10^{-6} \text{ emu/g}$, therefore $\mu_{\text{Co}}(2) = 0$. Our previous experimental data $\mu_{\text{Co}}(1) = 0.632 \mu_B$, and $\mu_{\text{Co}}(2) = 0.465 \mu_B$ were measured. We obtain $\mu_{\text{Co}}(0) + 3\mu_{\text{Co}}(1) = 2.53 \mu_B$ and $2.56 \mu_B$ by put-

FIG. 6. Temperature dependence of c axis for $\text{Gd}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ with $n = 2, 3$, and ∞ .

FIG. 7. Boron composition dependence of thermal expansion coefficients α_a and α_c . The data for $n=0$ are taken from Ref. 8.

ting the values of $\mu_{Co}(1)$ and $\mu_{Co}(2)$ mentioned above into Eq. (1), respectively. The obtained values of 2.53 and 2.56 are very close to each other, which means Eq. (1) is a good approximation. If $\mu_{Co}(0)$ is approximated by the Co moment of YCo_5 , $(1.55 \pm 0.10)\mu_B$ averaged over the five different data obtained in the previous work,⁷ we obtain $\mu_{Co}(1) = 0.33\mu_B$. The values of $\mu_{Co}(0) = 1.55\mu_B$, $\mu_{Co}(1) = 0.33\mu_B$ and $\mu_{Co}(2) = 0\mu_B$ are qualitatively supported by the energy band calculation³ for YCo_4B and YCo_3B_2 ; $\mu_{Co}(0) = 1.75\mu_B$, $\mu_{Co}(1) = 0.55\mu_B$ and $\mu_{Co}(2) = 0\mu_B$. To confirm if the above values are valid or not, neutron diffraction measurement will be performed. Equation (1) is based on the assumption that all crystallographic units A and B shown in Fig. 1 have approximately the same electronic state, respectively. Therefore all units A and B shown in Fig. 1 are considered to have the same thermal expansion coefficients $\alpha_c(A)$ and $\alpha_c(B)$ along the c axis, respectively. If $\alpha_c(A) = 15 \times 10^{-6} \text{ deg}^{-1}$ and $\alpha_c(B) = 28 \times 10^{-6} \text{ deg}^{-1}$ are assumed, the n -dependence of thermal expansion coefficient $\alpha_c(n)$ is calculated as shown by the bold solid line in Fig. 7. Agreement between the solid line and the observed values is good, which supports the assumption of Eq. (1). It is also noted that α_c and α_a for $GdCo_3B_2$ shows a clear contrast like the case of graphite⁵ whose linear thermal expansion coefficients at room temperature are $\alpha_c = 25.9 \times 10^{-6} \text{ deg}^{-1}$ and $\alpha_{\perp c} = -1.2 \times 10^{-6} \text{ deg}^{-1}$.

B. Spontaneous magnetostriction

It is noted that the spontaneous magnetostriction in Figs. 2 and 3 occurs only along the a axis (or in the c plane), which contrasts with the case of YCo_5 whose striction occurs only along the c axis.⁸ For this fact, the R-B layer(s) must play an important role, namely the strong covalent bond in the R-B layer disconnects the exchange interaction along the c axis. This is supported also by the drastic change of T_c between YCo_5 ($T_c = 980 \text{ K}$)⁷ and YCo_4B ($T_c = 380 \text{ K}$). The spontaneous magnetostriction of $GdCo_4B$ in Fig. 2 comes from the inter- and intrasublattice exchange interactions with exchange parameters J_{Gd-Co} , J_{Co-Co} , and J_{Gd-Gd} , while that of YCo_4B from intrasublattice interaction J_{Co-Co} only. The spontaneous magnetostriction $\omega_a (= \Delta a/a)$ can be expressed by the mean field model,⁹

FIG. 8. Spontaneous magnetostrictions for $GdCo_4B$ and YCo_4B obtained from Figs. 2 and 3. The solid lines are the calculated ones (see the text).

$$\omega_a = A_{Co-Co} M_{Co}^2 + B_{Co-Gd} M_{Co} M_{Gd} + C_{Gd-Gd} M_{Gd}^2, \quad (2)$$

where M_{Co} and M_{Gd} are the sublattice spontaneous magnetizations in the unit of $\mu_B/f.u.$, where $f.u.$ means RCo_4B , and A_{Co-Co} , etc., are constants proportional to products of $(c_{11} + c_{12})^{-1}$, and $\partial J_{Co-Co}/\partial a$, $\partial |J_{Gd-Co}|/\partial a$ and $\partial J_{Gd-Gd}/\partial a$, respectively, where c_{ij} is the elastic constant.⁹ Since temperature dependences of M_{Co} and M_{Gd} of $GdCo_4B$ and YCo_4B have been obtained,⁶ we can calculate ω_a for RCo_4B ($R=Gd$ and Y) as shown by the solid lines in Fig. 8. In this calculation, we take $A_{Co-Co} = 9.0 \times 10^{-5} \mu_B^{-2}$, $B_{Gd-Co} = 11.0 \times 10^{-5} \mu_B^{-2}$, and $C_{Gd-Gd} = -1.2 \times 10^{-5} \mu_B^{-2}$. The spontaneous magnetostrictions seem to be well expressed by Eq. (2). Since the values of M_{Co} and M_{Gd} at $T=0 \text{ K}$ were taken to be $2.53 \mu_B/f.u.$ and $7.0 \mu_B/f.u.$, the main contribution to the spontaneous magnetostriction is found to be the second term in Eq. (2). Since $B_{Gd-Co} \propto (c_{11} + c_{12})^{-1} (\partial |J_{Gd-Co}|/\partial a)$, the absolute value of J_{Gd-Co} increases with the a -axis expansion. The spontaneous magnetostriction of the Gd system with $n=2$ and $n=3$ are not clearly observed, as seen in Fig. 5. This fact can be explained by the increase of c_{ij} caused by the strong covalent bond in the R-B layer(s).

Specific-heat studies of RCu_4Al_8 compounds ($\text{R}=\text{Er}, \text{Y}$)

I. H. Hagmusa, F. E. Kayzel, E. Brück, and K. H. J. Buschow^{a)}

Van der Waals-Zeeman Institute, University of Amsterdam, Valckenierstraat 65, 1018 XE Amsterdam, The Netherlands

Specific-heat measurements have been performed on the tetragonal ThMn_{12} -type compound ErCu_4Al_8 and YCu_4Al_8 in the temperature range 1.5–200 K. A sharp peak in the specific heat, signals the antiferromagnetic transitions at $T_N = 5.18$ K. In order to separate out the effect of the Er sublattice we have also performed measurements on the YCu_4Al_8 compound in the same temperature range. From the temperature dependence of the magnetic contribution to the specific heat of ErCu_4Al_8 we obtained the temperature dependence on the magnetic entropy and discuss our results in terms of the crystal field level scheme proposed earlier from inelastic neutron scattering.

© 1998 American Institute of Physics. [S0021-8979(98)53411-1]

INTRODUCTION

Ternary-rare-earth compounds of the type RT_4Al_8 crystallize in the ThMn_{12} -type crystal structure in which rare-earth atoms occupy the $2a$ position, transition metal (T) the $8f$, and aluminum the $8i$ and $8j$ positions.^{1,2} They exist for several $3d$ transition elements including $\text{T}=\text{Cr}, \text{Mn}, \text{Fe}$, and Cu . The magnetic properties of these compounds depend strongly on the T component and vary between no magnetic ordering above 1.6 K for $\text{T}=\text{Mn}$ and magnetic-ordering temperatures well above 100 K for $\text{T}=\text{Fe}$. Much higher-ordering temperatures can be realized with the same structure type for compounds of compositions around $\text{RFe}_{10}\text{M}_2$ where $\text{M}=\text{Si}, \text{Ti}, \text{V}, \text{W}$, and Mo .³ Several of the latter compounds are considered as candidates for permanent-magnet materials and owe most of their magnetocrystalline anisotropy to the crystal-field induced R sublattice anisotropy. This crystal-field induced anisotropy is fairly complicated because it seems to be dominated by the contribution of higher-order-crystal-field parameters. The high-ordering temperatures of the $\text{RFe}_{10}\text{M}_2$ compounds prevent a thorough study of the crystal-field interaction in ThMn_{12} compounds. For this reason crystal-field studies have mainly concentrated on RT_4Al_8 representatives in which magnetic ordering occurs at very low temperatures or is absent altogether. In view of the many parameters involved, experimental information obtained by a technique complementary to the inelastic neutron scattering⁴ is desirable.

In the present investigation we report on specific-heat measurements performed in zero magnetic field on the ErCu_4Al_8 and YCu_4Al_8 compounds in the temperature range 1.5–200 K. The results are discussed in terms of the crystal-field-level scheme presently available from INS spectroscopy.⁴

EXPERIMENTAL DETAILS

The samples of the ErCu_4Al_8 and YCu_4Al_8 compounds were prepared in polycrystalline form by melting stoichiometric amounts of the elements (of at least 99.9% purity) in

an arc furnace under a reduced argon atmosphere. Vacuum annealing was performed at 800 °C for 6 weeks. Selected specimens of each sample were subsequently characterized by x-ray diffraction and were shown to be single phase with all Bragg peaks consistent with ThMn_{12} structure.

We have measured the specific heat in zero field in the temperature range from 1.5 to 200 K. About 200–400 mg of each compound were mounted on a sapphire plate in a thermal frame by using apiezone. This setup comprises the possibilities for measurements using the standard adiabatic method.

RESULTS AND DISCUSSION

The specific heat of the ErCu_4Al_8 and YCu_4Al_8 compounds has been measured at zero-magnetic field as a function of temperature. Plots of c/T vs T at zero field are given in Fig. 1. The data shown for ErCu_4Al_8 are characterized by

FIG. 1. Temperature dependence of the specific heat (c/T) of the ErCu_4Al_8 and YCu_4Al_8 compounds.

^{a)}Electronic mail: buschow@phys.uva.nl

FIG. 2. Temperature dependence of the specific heat (c) of YCu_4Al_8 . The thin solid curve represents a fit to the data points made on the basis of Eq. (1).

a sharp anomaly at 5.18 K. This anomaly is attributed to antiferromagnetic ordering. A Néel type transition at $T_N = 6$ K has also been observed by magnetic measurements,⁵ and the antiferromagnetic nature of the magnetic ordering has been confirmed by neutron diffraction experiment performed by Baio *et al.*⁶

As seen in Fig. 1, no peak is observable in the same temperature range for YCu_4Al_8 . The specific-heat data of this compound have been analyzed by using the formula

$$c = \gamma T + 9Nk_B(T/\Theta_D) \int_0^{\Theta_D/T} \frac{x^4 e^x dx}{(e^x - 1)^2} \quad (1)$$

where γ is the electronic specific-heat coefficient and Θ_D the Debye temperature. From a plot of c/T vs T^2 of the low-temperature data, we have determined γ to be equal to $0.02 \text{ J/K}^2\text{mol}$. From fitting the specific heat curve over the whole temperature range considered we derived $\Theta_D = 375 \text{ K}$. The experimental data and the calculated curve are compared in Fig. 2. These data were subsequently used to separate out the magnetic contribution to the specific heat of the Er sublattice.

In Fig. 3 we have plotted the temperature dependence of c_m/T , where c_m is the magnetic specific heat for the ErCu_4Al_8 compound, obtained by subtracting the nonmagnetic part from the observed specific heat. These data have been used, in turn, to obtain the temperature dependence of S_m/R , where S_m is the magnetic entropy. The temperature dependence of S_m/R is also shown in Fig. 3.

The crystal field splitting in the ErCu_4Al_8 compound was studied earlier by inelastic neutron scattering (INS) experiments.⁴ These experiments had led to propose a level scheme in which the ground state is a doublet state, particularly rich in $|J_z = \pm 7/2\rangle$. The first excited level, lying at about 42 K from the ground state, is a doublet dominated by the $|J_z = \pm 9/2\rangle$ wave function. The overall crystal field splitting is about 313 K. The magnetic ordering at about 5.2 K involves therefore mainly the isolated ground state doublet.

FIG. 3. Temperature dependence of the magnetic contribution to the specific heat (c_m/T) of ErCu_4Al_8 (left scale). The thin solid curve represents the temperature dependence of the magnetic entropy (right scale).

The entropy reached at the magnetic transition is expected to be equal to $R \ln 2 = 0.7$, which is in satisfactory agreement with the data shown in Fig. 3. It can furthermore be seen in Fig. 3 that in the paramagnetic regime a small Schottky anomaly is found, leading to a shallow maximum in the specific heat curve at about 25 K. It is well known that Schottky anomalies of this type are generally observed at temperatures roughly halfway in temperature between the ground state and the first excited state. The specific heat data are therefore in reasonable agreement with the level separation of 42 K mentioned above. Finally, at high temperatures, the entropy is expected to reach its maximum value $R \ln(2J+1)$. For Er with $J = 15/2$ this maximum value corresponds to $S_m/R = \ln(16) = 2.77$. This value is seen in Fig. 3 to be reached at 100 K. We previously mentioned that the INS measurements had indicated an overall crystal field splitting of 313 K and from the corresponding level scheme it can be derived that at 100 K only about half of the levels will be populated. At first sight this seems to be in conflict with the entropy data presented in Fig. 3. However, one has to bear in mind that the magnetic contribution to the specific heat of ErCu_4Al_8 has been obtained by using the YCu_4Al_8 data for estimating the phonon contribution. In view of the large difference in atomic weight between Er and Y, the phonon contribution based on the YCu_4Al_8 data very likely is underestimated. It means that the magnetic contribution of ErCu_4Al_8 is somewhat too large, in particular in the high-temperature regime. This, in turn, leads to an overestimation of S_m/R in the high-temperature part and causes the apparent discrepancy with the INS data. An extension of our specific heat measurements to more compounds of this series is planned in the near future.

Magnetic and structural properties of commercial $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ -based magnets

X. Chen, J. F. Liu, C. Ni, and G. Hadjipanayis^{a)}

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716-2570

A. Kim

YBM MAGNEX, Inc., 110 Terry Drive, Newtown, Pennsylvania 18940

A newly developed $\text{Sm}(\text{Co,Fe,Cu,Zr})_z$ magnet, with $z \approx 7$, has a lower temperature coefficient of coercivity β , as compared with other commercial magnets with $z \approx 7.7$. It was found that the initial magnetization curve for the newly developed magnet is typical of pure uniform domain wall pinning, while for the commercial magnets nucleation and domain wall pinning occur simultaneously, although domain wall pinning is still the dominant mechanism. It was also found that the magnetic viscosity parameter S_v has similar temperature dependence with the coercivity. Transmission electron microscope studies showed that the smaller cell size contributes to the low temperature coefficient of coercivity. © 1998 American Institute of Physics.

[S0021-8979(98)20011-9]

I. INTRODUCTION

In permanent magnets, the coercivity and remanence decrease with increasing temperature with rates, known as temperature coefficients, given by $\beta = dH_c/dT$ and $\alpha = dM_r/dT$, respectively. $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets so far have the lowest temperature coefficient among rare-earth permanent magnets, and hence, they are very promising candidates for high temperature applications. The coercivity temperature coefficient β ($\sim 0.3\%/^\circ\text{C}$) is much higher than the remanence temperature coefficient α ($\sim 0.03\%/^\circ\text{C}$), and because of this, the coercivity is reduced more rapidly with increasing temperature than the remanence. The low coercivities at high temperatures lead to a very low energy product and limit the high temperature applications of these magnets.

The coefficient β is strongly dependent on the magnetization reversal mechanism, which is sensitive to the magnet composition, processing parameters, microstructure, and microchemistry of the phases present. Earlier studies showed that SmCo_5 , SmTM_7 , and $\text{SmTM}_{7.43}$ magnets have different high temperature behavior.¹ Recent studies showed that the high temperature performance of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ -based magnets is very sensitive to the iron content. High iron content resulted in a greater irreversible loss.² A $\text{Sm}(\text{Co,Fe,Cu,M})_7$ magnet, where M is at least one or a combination of Zr, Hf, Ti, Mn, Nb, V, Mo, and W, was found to effectively reduce the temperature coefficient of coercivity with a moderately high room temperature coercivity (~ 20 kOe) and good loop squareness.³ But it is not yet clear why their high temperature behavior is different. A systematic investigation of magnetic and structural properties of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ -based magnets is needed in order to understand their high temperature behavior and find a way to improve their performance at temperatures above 400°C .

II. EXPERIMENT

Several $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ -based magnets from Crucible, EEC, and Arnold were used to study and understand the temperature dependence of magnetic properties up to 600°C . The crystallographic structure was studied using a Philips x-ray diffractometer. The magnetic properties at and below room temperature were tested using a superconducting quantum interference device (SQUID) magnetometer with a maximum applied field of 55 kOe. High temperature magnetic properties were measured using a vibrating sample magnetometer (VSM). Microstructure analysis was carried out using a JEOL JEM-2000FX transmission electron microscope (TEM). Magnetic viscosity measurements were carried out using the VSM.

III. RESULTS AND DISCUSSION

A. Temperature dependence of magnetic properties

All the as-received magnets had the $\text{Th}_2\text{Zn}_{17}$ rhombohedral structure. A typical x-ray diffraction pattern is shown in Fig. 1. The commercial $\text{Sm}(\text{Co, Fe, Cu, Zr})_z$ magnets with $z \approx 7.7$ received from different companies were designated as C1, C2, C3, and C4, the Crucible newly developed magnet with $z \approx 7$ was designated as N1. The Curie temperature, saturation magnetization at 55 kOe, intrinsic coercivity $H_{ci}(\text{RT})$ and $H_{ci}(450^\circ\text{C})$, and temperature coefficient of co-

FIG. 1. Typical x-ray pattern of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets.

^{a)}Electronic mail: hadji@udel.edu

TABLE I. Curie temperature T_c , saturation magnetization M_s at 55 kOe, intrinsic coercivity H_{ci} at room temperature and 450 °C, and the temperature coefficient of coercivity β for $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_z$ magnets.

Sample	T_c (°C)	M_s (emu/g)	H_{ci} (RT) (kOe)	H_{ci} (450 °C) (kOe)	β (%/°C) (RT-450 °C)
C1	810	104	22.6	3.5	-0.20
C2	811	104	23.1	2.9	-0.20
C3	818	112	34.3	3.2	-0.21
C4	815	103	27.7	2.6	-0.21
N1	810	93	19.6	6.2	-0.16

ercivity $\beta(\text{RT}-450^\circ\text{C})$ for all the received magnets were measured and listed in Table I. The temperature coefficient of coercivity ($\text{RT}-T_1$) is calculated using the following formula: $\beta(\text{RT}-T_1) = \{[H_{ci}(\text{RT}) - H_{ci}(T_1)]/[H_{ci}(\text{RT}) \times (\text{RT} - T_1)]\} \times 100\%$, where T_1 is the operation temperature. The Curie temperature for all the samples is above 800 °C with small differences of less than 10 °C. A single value of Curie temperature for each sample was identified during measurements. Sample N1 has the highest coercivity at 450 °C and lowest temperature coefficient of H_{ci} . The temperature dependence of coercivities for all the samples is shown in Fig. 2. It is interesting to note that sample N1, with a H_{ci} of 6.2 kOe at 450 °C, has the lowest coercivity at room temperature, while sample C3, with a H_{ci} of only 3.15 kOe at 450 °C, has the highest coercivity at room temperature. Therefore, high room temperature coercivity does not necessarily mean high coercivity at higher temperatures.

B. Initial magnetization curves

Figure 3 shows the normalized initial magnetization curves at room temperature. Samples N1, which has the highest coercivity above 400 °C, and C1 to C4, which have very low coercivity above 400 °C, show a strong pinning dominated initial magnetization curve, but if we take a closer look at the initial curves, they are different. The initial curve for N1 is typical of pure uniform strong domain wall pinning, while the initial curve for sample C3 is typical of mixed pinning and nucleation mechanisms. Nucleation and domain wall movement occurs at very low applied fields and then the domain wall is pinned by strong pinning sites. For samples C1, C2, and C4, local nucleation and domain wall

FIG. 3. Normalized initial magnetization curves at room temperature.

pinning processes occur simultaneously, although, in general, it is still dominated by a strong domain wall pinning mechanism.

We believe that pure and uniform strong domain wall pinning is a critical factor for high coercivity at high temperatures for $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_z$ magnets.

C. Magnetic viscosity analysis

Magnetic viscosity analysis is another way to understand the behavior of magnetization reversal. From the logarithmic dependence of magnetization, the magnetic viscosity coefficient $S = -dM/d \ln(t)$ can be obtained. S is related to the magnetic viscosity parameter (S_v) through the equation $S_v = S/\chi^{\text{irr}}$, where χ^{irr} is the irreversible susceptibility.⁴ Magnetic viscosity measurements were carried out for two typical samples. The detailed measurement method was described elsewhere.⁵ Figure 4 shows the temperature dependence of magnetic viscosity parameter S_v .

The magnetic viscosity parameter S_v for sample N1, which has the highest coercivity at 450 °C, is less temperature dependent, as compared to the C4 sample, which has the lowest coercivity at 450 °C. This result indicates that the magnetic viscosity parameter S_v and coercivity H_{ci} have a similar temperature dependence.

D. Microstructure comparison

TEM analysis showed a similar microstructure for all the 2:17 magnet samples, consisting of a mixture of cellular and

FIG. 2. Temperature dependence of coercivity.

FIG. 4. Temperature dependence of the magnetic viscosity parameter S_v .

TABLE II. Comparison of microscopic features.

Sample	Phases identified	Cell size (nm)	Wall thickness (nm)	Density of lamella
N1	2:17 & 1:5	43	6–15	Low
C1	2:17 & 1:5	63	5–20	High
C2	2:17 & 1:5	75	10–40	High
C4	2:17 & 1:5	80	2–12	High

lamellae structure. A statistical analysis was performed on the cellular and lamellae structure. Table II shows the cell size, the cell boundary thickness, and the density of the lamella phase for all the samples. The microstructure of samples N1 and C2 is shown in Fig. 5. Sample N1, which

FIG. 5. Microstructure of samples (a) C2 and (b) N1.

has the highest coercivity at 450 °C and lowest temperature coefficient of coercivity β , has the smallest cell size. It should be noted that sample N1 has relatively higher Sm content than all the other samples, and this would help to form more 1:5 cell boundaries according to the phase diagram. Therefore, smaller cells could be expected after a suitable heat treatment. Smaller cell size contributes to a high coercivity at high temperatures. The smaller the cell, the stronger and more uniform the domain wall pinning, and this is confirmed by their initial magnetization curves. All the samples with high density of lamella precipitates have higher coercivity at room temperature. The density of lamella phase can increase the room temperature coercivity but has little contribution to the coercivity at high temperatures, indicating that the pinning force of this lamella phase decreases rapidly as the temperature increases. Smaller cell size is another key feature for the magnets with high temperature performance.

IV. CONCLUSION

The temperature coefficient of coercivity β is a very important factor for the high temperature performance of commercial $\text{Sm}_2(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_{17}$ -based magnets. Commercial samples with $z \approx 7.7$ showed a $\beta(\text{RT} - 450^\circ\text{C}) = -0.2\%/^\circ\text{C}$, which resulted in a H_{ci} of about 3 kOe at 450 °C. However, magnet N1 with $z \approx 7$ gave a $\beta(\text{RT} - 450^\circ\text{C})$ of $-0.16\%/^\circ\text{C}$, resulting in a H_{ci} of about 6.2 kOe at the same temperature. It was found that the initial magnetization curve for the magnet with high coercivity at 450 °C is typical of pure strong uniform domain wall pinning, while for the magnet with a low coercivity at 450 °C is typical of mixed mechanism although it is still dominated by domain wall pinning. It was also found that the magnetic viscosity parameter S_v is less temperature dependent for the magnets with a higher coercivity at high temperatures. TEM studies showed that smaller cell sizes have a contribution to high coercivity at high temperatures, while a higher density of the lamella phase leads to higher coercivity at low temperatures.

The magnetization study of melt-spun ribbons of B containing TbFe₂ alloys

K. S. Kim and S. C. Yu^{a)}

Department of Physics, Chungbuk National University, Cheongju 361-763, Korea

S. R. Kim and S. H. Lim

Thin Film Technology Center, Korea Institute of Science & Technology, Seoul, 130-650, Korea

We have carried out the magnetization study of melt-spun ribbons of $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1, \text{ and } 0.15$) alloys. The temperature dependence of magnetization was measured using a superconducting quantum interference device and a vibrating-sample magnetometer during heating from 5 to 800 K, with an applied field of either 10 or 50 kOe. The present study shows the existence of noncollinear magnetic structures. From an analysis of the approach to saturation magnetization, the average magnetic moment μ_a , random anisotropy field H_r , and local random anisotropy constant K_L have been extracted. It is found that μ_a decreases from 1.68 ($x=0$) to 1.33 μ_B ($x=0.15$) and K_L increases with increasing B concentration. This result suggests that the addition of B seems to increase the random anisotropy and hence to decrease the magnetic order, resulting a sperimagnet with large spread angle. © 1998 American Institute of Physics.

[S0021-8979(98)49411-8]

I. INTRODUCTION

Cubic Laves phase TbFe₂ compound is known to exhibit the largest magnetostriction at room temperature.¹ Nanocrystalline grain structure in TbFe₂-B alloys was by crystallization a melt-spun amorphous phase² and the alloy with nanocrystalline grain structure was found to exhibit better magnetostrictive characteristics at low magnetic fields than for bulk TbFe₂ alloy. Recently, it was shown for giant magnetostrictive RE-Fe [(RE) rare earths] based alloys that homogeneous and ultrafine grains were obtained even in the as-spun state.³ This was made possible at a suitable quenching rate, together with the addition of a suitable amount of B to RE-Fe alloys. We therefore find it appropriate to investigate in detail the magnetic properties of melt-spun $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1, \text{ and } 0.15$) alloys. Abnormal behavior in the temperature dependence of magnetization measured at 10 kOe is observed in all the specimens. Magnetization is very small at low temperatures and it initially increases with increasing temperature, reaches a maximum, and then decreases with the further increase of temperature. This result may be explained by strong random anisotropy at low temperatures. In the framework of the two sublattice model, the abnormal magnetization behavior can be explained in terms of the existence of the conical spin structure which is caused by the noncollinear magnetic couplings between Fe atoms, and between Tb atoms due to the structural disorder. It is noted that the spins from Tb and Fe atoms couple antiferromagnetically. In this article, in order to obtain intrinsic magnetic properties we analyzed the temperature and field dependence of magnetization of melt-spun ribbons of B containing TbFe₂ alloys.

II. EXPERIMENT

The Tb-Fe-B alloys were arc melted in an Ar atmosphere and, in some cases, the alloy ingots were also ob-

tained by induction melting. Subsequent melt spinning was carried out in an Ar atmosphere with a surface velocity of 50 m/s. The melt temperature was maintained at just above the melting point. The ribbons obtained were 20 μm thick and about 1 to 2 mm wide. The structure of the samples was examined by x-ray diffraction using Cu $K\alpha$ radiation and also by transmission electron microscopy (TEM). The formation of an amorphous phase was observed more clearly from TEM. A previously TEM study³ showed that the melt-spun ribbons consists of nanocrystalline grains and an amorphous phase. The magnetization measurements were performed by using a superconducting quantum interference device (SQUID) and a vibrating-sample magnetometer (VSM) during heating from 5 to 800 K, with an applied field of either 10 or 50 kOe.

III. RESULTS AND DISCUSSION

A. Temperature dependence of magnetization

Figure 1 shows the temperature dependence of magnetization for the melt-spun $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1, \text{ and } 0.15$) alloys at 10 kOe. It can be seen in all the curves that the magnetization increases with increasing temperature and reaches a maximum at a temperature T_{max} , above which the magnetization starts to decrease, as expected, upon approaching the Curie temperature T_c . It seems that the applied field of 10 kOe is not enough to magnetize the specimens at low temperatures. With increasing B content, the magnetization at T_{max} decreases from 90 ($x=0$) to 72 emu/g ($x=0.15$). In the framework of the two sublattice model, the abnormal behavior of these magnetization curves can be explained in terms of the existence of noncollinear magnetic structures. Figure 1 shows the temperature dependence of magnetization for the same samples at a higher magnetic field of 50 kOe. As can be seen in Fig. 2, the temperature dependence of magnetization at an applied magnetic field of 50 kOe becomes similar to that observed in normal ferromagnets or ferrimagnets.

^{a)}Electronic mail: scyu@cbucc.chungbuk.ac.kr

FIG. 1. The temperature dependence of magnetization for the melt-spun ribbons of $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1$, and 0.15) alloys at an applied magnetic field of 10 kOe.

Figure 3 represents the magnetization at 5 K with an applied field of 50 kOe and the Curie temperature as a function of B concentration. It is seen from Fig. 3 that the magnitude of magnetization decreases monotonically with the increase of B. At low temperatures, the magnetization $M(T)$ is well described in terms of the Bloch's $T^{3/2}$ law. The Bloch coefficients B , which is the thermal average of the total contribution arising from spin waves of all wavelengths, is related to the spin wave stiffness D , through the expression⁴

$$D = \zeta(3/2)^{2/3} [g \mu_B / M(0) B]^{2/3} (k_B / 4\pi), \quad (1)$$

where $\zeta(3/2)$ is the Riemann zeta function and g is the spectroscopic splitting g factor. The values of D were determined from a fit to the SQUID magnetic data measured at 50 kOe in the temperature range 5–200 K. It is found that the value of D decreases from 126.8 to 65.1 meV \AA^2 with increasing B concentration from $x=0$ to $x=0.15$. This may be due to the increasing proportion of negative Fe–Fe interactions at short interatomic separations and the decrease of average

FIG. 2. The temperature dependence of magnetization for the melt-spun ribbons of $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1$, and 0.15) alloys at an applied magnetic field of 50 kOe.

FIG. 3. The magnetization measured at the temperature of 5 K and at the field of 50 kOe, and the Curie temperature as a function of B concentration.

iron moment. In order to clarify this behavior, we estimated the exchange stiffness A and the average moment of the samples. The value of A can be obtained from the mean field model and from the Curie temperature.^{5,6} One can drive the following relation

$$A = (C S_{\text{Fe}} k_B T_c) / 4(S_{\text{Fe}} + 1) r_{\text{Fe-Fe}} \quad (2)$$

where C is the concentration of Fe in atomic percent, S_{Fe} is the spin moment of Fe and $r_{\text{Fe-Fe}}$ is the nearest neighbor distance. We can calculate S_{Fe} , from the relation of $M(\mu_B) = 2x_{\text{Fe}} S_{\text{Fe}} \mu_B$, where $M(\mu_B)$ and x_{Fe} are the magnetic moment of sample and the concentration of Fe, respectively. The magnetic moment arises from the contribution of the moments of Fe (μ_{Fe}) and Tb (μ_{Tb}), which are aligned antiferromagnetically. It is known that the transition metal (TM) moment is reduced when RE is alloyed. This is due to the hybridization of the $3d$ orbitals of TM with the $5d$ ones of RE. We found $\mu_{\text{Tb}} = 0.64 \mu_B$ in $\text{Tb}_{0.33}\text{Fe}_{0.67}$ alloy. This value is lower than the theoretical value expected for the free ion Tb ($9.0 \mu_B$). This suggests that the spin structure of Tb is not collinear but conical. This is to be expected for the rare earth with a strong spin-orbit coupling and hence strong random local anisotropy. An independent estimate of exchange integral J is provided by the expression for the Curie temperature in the molecular field approximation. It is known that the exchange integral between two Fe atoms depends sensitively on the relation between their interatomic separation and the range of their $3d$ orbitals. Exchange integral J is described in terms of the Curie temperature

$$T_c = 2 \langle Z \rangle J_{\text{Fe-Fe}} S_{\text{Fe}} (S_{\text{Fe}} + 1) / 3k_B. \quad (3)$$

Figure 4 shows the exchange constant and exchange integral as a function of the B content. It is seen from Fig. 4 that both the exchange stiffness constant and the exchange integral decrease with increasing B concentration. This result can be expected from the suppression of the magnetic random anisotropy in the B-free sample, thus the random magnetic anisotropy seems to be minimized. In order to clarify this behavior, we analyzed the field dependence of magnetization.

FIG. 4. The exchange stiffness constant and the exchange integral as a function of B concentration.

B. Field dependence of magnetization

According to the Chudnovsky model,^{7,8} for applied fields less than the exchange field H_{ex} , magnetization shows a linear dependence on $H^{1/2}$. It is known that magnetization can be written phenomenologically as

$$M = M_s(1 - a_1/H^{1/2} - a_2/H - a_3/H^2) + \chi_{hf}H. \quad (4)$$

The terms involving a_1 and a_2 result from the fluctuations of the local orientation of the easy axis and structural inhomogeneities, respectively. The term a_3/H^2 is ignored in our calculations, because in our case the applied field is not so high. χ_{hf} is the high field magnetic susceptibility. The magnetization curves for all samples are found to fit Eq. (4) as shown in Fig. 5. From the fit, one can deduce the field H_s , where $H_s = H_r/H_{ex}^3$. The random anisotropy field H_r and the local random anisotropy constant K_L are related as $H_r = 2K_L/M_0$. The exchange field can also be expressed as $H_{ex} = 2A/M_0(R_a)^2$, where R_a is the atomic correlation

FIG. 5. The field dependence of magnetization at 5 K for the melt-spun ribbons of $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1$, and 0.15) alloys. The solid lines represent the fit of the data to Eq. (4).

TABLE I. The values of average magnetic moment (μ_a), average half cone angle (θ) of the iron subnetwork, exchange field (H_{ex}), anisotropy field (H_r), and random anisotropy constant (K_L) for the melt-spun ribbons of $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$ ($x=0, 0.02, 0.05, 0.1$, and 0.15) alloys.

$(\text{Tb}_{0.33}\text{Fe}_{0.67})_{1-x}\text{B}_x$	μ_a (μ_B)	θ ($^\circ$)	H_{ex} (T)	H_r (T)	K_L (10^6 erg/cm ³)
$x=0$	1.68	58	2.6	0.4	2.1
$x=0.02$	1.62	62	2.5	0.6	3.1
$x=0.05$	1.52	68	2.1	1.0	5.0
$x=0.1$	1.40	74	2.0	1.1	5.3
$x=0.15$	1.33	78	1.9	1.3	6.2

length, taken generally as 10 \AA in the case of an amorphous phase.⁹ The values of H_{ex} and μ_a decrease with increasing B concentration. This indicates that the magnetic structure of these alloys changes with the addition of B. The decrease of H_{ex} and the increase of H_r with increasing B concentration can be explained by the conical magnetic structure with larger spread angle at higher B content. The present result shows that the random magnetic anisotropy increases with increasing B content. Indeed, it is seen in Table I that the average magnetic moment decreases from 1.68 to $1.33 \mu_B$ and the local random magnetic anisotropy constant K_L increases with increasing B content. Using the relation¹⁰

$$\mu_{Fe} = \mu_{Fe}(\text{free ion})(1 + \cos \theta)/2 \quad (5)$$

the average half cone angle is estimated to be 58° for the iron subnetwork in the B-free sample. This indicates that the Fe moments have a conical spin structure due to strong random anisotropy. The reduction in the Fe moment arises from the random local anisotropy which tends to align the Fe moment along random directions. In particular, one observes that the spread angle increases with increasing B content. This result is consistent with the observation that the local random magnetic anisotropy increases with increasing B content. It would be of interest to compare the present results with those reported previously³ where magnetostriction decreases with increasing B content.

The effect of Ga substitution for Fe in $\text{Dy}_2\text{Fe}_{17-x}\text{Ga}_x$ on the low field ac susceptibility is reported. The easy magnetization direction is along the c axis for $x > 6.3$ while for $x < 6$ it is within the basal plane. With decreasing temperature a spin reorientation from an easy axis to an easy cone takes place when $6 \leq x \leq 6.3$. Two other anomalies have been found in the susceptibility of easy plane materials when the field is applied in the plane: (i) at T near room temperature, both χ' and χ'' depend on the frequency and χ'' shows a maximum which shifts to higher temperatures with increasing frequency; (ii) at low temperatures an increase in χ' is accompanied by time varying effects. While the latter is related to the domain structure reconstruction due to a change of the in-plane anisotropy, the former is caused by thermally activated domain wall pinning and depinning. The Ga substitution strongly affects the low temperature anomaly which disappears when $x > 2$, whereas it has little effect on the high temperature one. © 1998 American Institute of Physics. [S0021-8979(98)30011-0]

INTRODUCTION

Substitution of some Ga for Fe in R_2Fe_{17} can effectively increase the Curie temperature and induce room temperature uniaxial anisotropy.¹⁻⁵ However, the reasons for these changes are not quite clear. Temperature dependence of anisotropy constants is one among many studies which may help to understand the origin of the change of anisotropy type. When such changes take place upon substitution, a temperature-induced spin reorientation transition (SRT) can be expected for certain compositions.

Owing to the direct relation between domain-magnetization-rotation (DMR) susceptibility, and the anisotropy constants \mathbf{K}_i and spontaneous magnetization \mathbf{M}_s , the low-field ac-susceptibility technique is often used to detect SRT caused by change in the anisotropy energy. However, there can also be a contribution to the ac susceptibility from domain-wall displacement (DWD), which makes the analysis complicated, since factors other than the intrinsic parameters \mathbf{M}_s and \mathbf{K}_i will play a role. Thus different types of anomalous temperature dependence could arise, which cannot be directly related to \mathbf{K}_i and explained by the classical technical magnetization theories for DWD. Susceptibility anomalies have been found in a number of rare earth-transition metal based alloys and have received different, sometimes controversial, explanations in the literature.⁶⁻⁹

Here we present the results from an ac-susceptibility search for spin reorientation transitions in $\text{Dy}_2\text{Fe}_{17-x}\text{Ga}_x$ in which an anomalous temperature dependence of χ_{ac} was also found and studied.

EXPERIMENTAL METHODS

The real χ' and imaginary χ'' components of the ac susceptibility ($\chi = \chi' - j\chi''$) have been measured at an ac-

field amplitude of $H_m = 8$ A/m and fixed frequencies f between 10 and 1000 Hz using a mutual impedance bridge. Measurements were taken while warming the samples at a constant rate from 4.2 K (for some samples from 77 K) after zero field cooling. Measurements above room temperature on bulk polycrystalline samples have been taken only at $f = 100$ Hz with a setup different from the one used at low temperatures.

Oriented samples with a cylindrical shape ($l = 10$ mm, $d = 3$ mm) have been prepared by mixing 10%–15% fine powder (particle size under $15 \mu\text{m}$) with epoxy resin, followed by alignment in a 1 T magnetic field in two different ways depending on the type of the room temperature magnetic anisotropy. For alignment of easy axis materials ($x \geq 6$) a static magnetic field was applied, while for the easy plane materials ($x < 6$) a rotating field was used¹⁰ to insure that the magnetically hard c axis of all crystallites is collinear.

For calculating χ_{ac} , the sample volume was determined by the mass-density technique using the net mass and x-ray density. No demagnetizing corrections were performed (the demagnetizing factors are smaller than 0.05).

RESULTS AND DISCUSSION

Above room temperature, χ_{ac} for all samples changes smoothly without any indication of SRT up to the Curie temperature, at which temperature a Hopkinson type maximum occurs. This shows that the room temperature anisotropy type is maintained. The measured T_c are in good agreement with those reported by Shen *et al.*²

Below room temperature, depending on the Ga concentration, four different types of behavior were found.

- (1) For all samples with Ga above $x = 6.3$ (i.e., $x = 6.8$; 7 and 8) χ' is very small (less than 0.1) and changes smoothly without any peculiarities, regardless of the direction of

^{a)}Electronic mail: jcoey@tcd.ie

FIG. 1. χ'' as a function of temperature measured at $H_m = 8$ A/m. The field is applied perpendicular to the easy c axis.

the applied field. The easy magnetization direction is along the c axis for all temperatures. The small value of χ' reflects the uniaxial character of the anisotropy and the reduced value of M_s , due to the combined effects of Ga dilution and antiparallel coupling of the rare earth and Fe sublattices.

- (2) For $x=6$ and 6.3 a sharp peak on transverse χ' appears at temperatures of 116 and 110 K, respectively; see Fig. 1. The peak position and the susceptibility itself are frequency independent. It is natural to attribute this peak to a SRT, at which deviation of the moments from the easy c axis takes place with decreasing temperature. This attribution is supported by the magnetization and Mössbauer data obtained on oriented samples, suggesting that below the SRT the magnetic moments are along an easy cone. It is worth noting that the change of the anisotropy type in $\text{Dy}_2\text{Fe}_{17-x}\text{Ga}_x$ takes place at a lower Ga concentration than in $\text{Y}_2\text{Fe}_{17-x}\text{Ga}_x$, where \mathbf{K}_1 of the Fe sublattice has been found⁵ to change sign slightly above $x = 6.5$.
- (3) For easy plane samples with Ga above $x=2$, χ_{ac} measured with the field applied in the easy plane is an order of magnitude higher than that for easy axis materials, Fig. 2(c). With increasing temperature χ' increases. At low T all the curves measured at different frequencies coincide, while above about 230 K they depend strongly on f but tend to merge again when approaching room temperature. In the latter region χ'' starts to increase from a negligible value and forms a peak, Fig. 3(c). Both the χ'' peak and the χ' curve shift to higher T for higher f .
- (4) For $\text{Dy}_2\text{Fe}_{17}$ and for samples with $x=1$ and 2 (all of them with easy plane anisotropy) another anomaly appears between 145 and 155 K, where the parallel χ' forms a dip (for the Ga-free sample) or shoulder (for $x = 1$ and 2). In this temperature region χ' depends on the warming rate and it also decays with time.

If the field is applied perpendicular to the easy plane materials, χ_{ac} for all of them is much smaller, Fig. 2(b), and it changes smoothly without any anomaly.

Similar anomalous behavior has already been observed in $\text{Sm}_2\text{Fe}_{17}$ and discussed extensively in the literature.⁶⁻⁹ In a recent publication⁹ Chen, Skumryev, and Coey emphasized the difference between the high and low temperature anomalies. They suggested that the latter is related to domain struc-

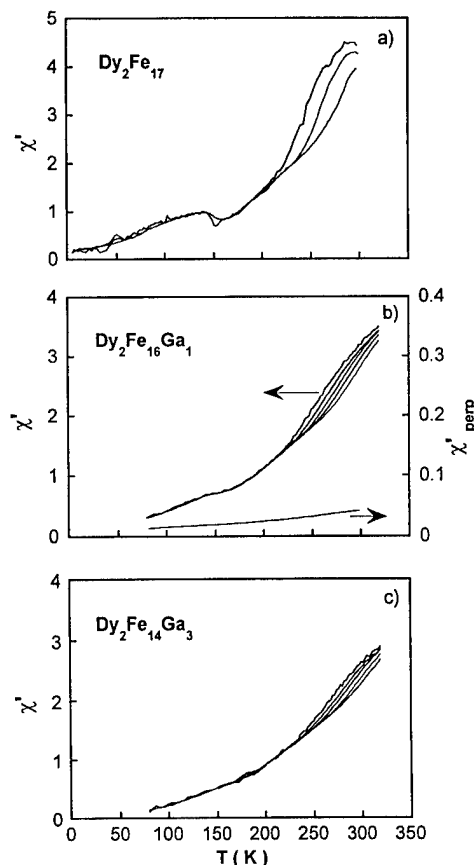

FIG. 2. χ' as a function of temperature at $H_m = 8$ A/m, applied along ab plane, for different frequencies: (a) $f = 10, 100$ and 1000 Hz; (b) and (c) $f = 10, 30, 100, 300$, and 1000 Hz. The curves shift to higher T at greater f . On the right-hand y axis of (b) χ' measured with field along the hard c axis is plotted.

ture reconstruction accompanied by thermally hysteretic pseudostatic wall pinning and depinning, whereas the former is caused by thermally activated dynamic domain wall pinning and depinning due to local directional ordering around domain walls.

In order to trigger the low temperature anomaly a sudden change in the domain structure is required. For easy plane anisotropy materials, where most domain walls lie in the ab plane, such a change could arise if the in-plane anisotropy constant \mathbf{K}_3 changes rapidly. Indeed, for a $\text{Dy}_2\text{Co}_{17}$ single crystal a drop in χ' was observed at temperatures where \mathbf{K}_3 vanishes.⁷ For $\text{Dy}_2\text{Fe}_{17-x}\text{Ga}_x$ easy plane materials we found that \mathbf{K}_1 and \mathbf{K}_2 decrease with Ga substitution. Although it was not possible to determine \mathbf{K}_3 for our polycrystalline samples, we can expect that Ga substitution would also affect the in-plane anisotropy constant and hence the low temperature anomaly. Indeed, as we see from Fig. 2, the anomaly is strongly affected by Ga substitution and disappears above $x=2$.

The high temperature anomaly could be caused by thermally activated local directional ordering of Fe atoms or a small amount of hydrogen in the sample,⁹ and it has no direct relation to the change in the anisotropy energy affected by Ga. Indeed, as can be seen from Figs. 2 and 3, Ga substitution has little effect on it. The anomaly was observed for all samples with an easy plane anisotropy. Using the set of data

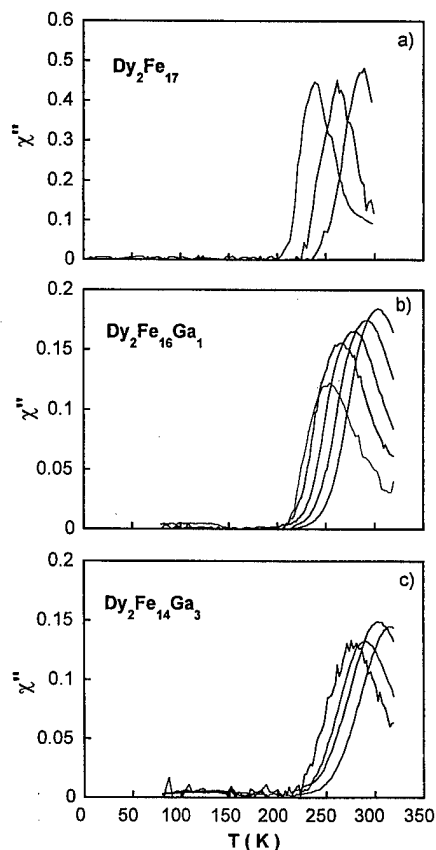

FIG. 3. χ'' as a function of temperature at $H_m = 8$ A/m, applied along ab plane, for different frequencies: (a) $f = 10$, 100 and 1000 Hz; (b) $f = 10$, 30, 100, 300, and 1000 Hz; (c) $f = 30$, 100, 300, and 1000 Hz. The curves shift to higher T at greater f .

for χ' and χ'' measured on $\text{Dy}_2\text{Fe}_{16}\text{Ga}_1$ [Figs. 2(b) and 3(b)] and following the procedure described in Ref. 9 χ'' vs χ' plots were obtained for fixed temperatures between 250 and 290 K. Most points fits on a semicircle, which suggests the existence of single relaxation time τ for a thermally activated process at a given temperature. The relaxation time obeys an

Arrhenius law with an activation energy $Q \approx 0.5$ eV and a pre-exponential factor $\tau_0 \approx 2 \times 10^{-13}$, which is characteristic of a Debye process.

CONCLUSION

It has been found that for all temperatures below T_c the easy magnetization direction is along the c axis for Ga substitution $x > 6.3$ while for $x < 6$ it is within the basal plane. With decreasing temperature a spin reorientation from an easy axis to an easy cone takes place in a narrow compositional range between $x = 6$ and $x = 6.3$. Two other anomalies in the susceptibility of easy plane materials have been found when it is measured in a field within the plane. The Ga substitution strongly affects the low temperature anomaly which disappears above $\text{Ga} = 2$, whereas it has little effect on the high temperature one.

The thermal diffusivity of bulk and epitaxial layer samples of the giant magnetoresistance compounds $\text{Nd}_{0.67}\text{Sr}_{0.33}\text{MnO}_{3-\delta}$ and $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3-\delta}$ is investigated in a comparative study for temperatures between 35 and 350 K in order to detect preparational differences and to correlate the thermal transport with magnetization M and resistivity ρ . We find for Nd–Sr an anomaly of the heat diffusivity D near 145 K (80 K La–Ca) which we attribute to a temperature-induced canted metal to AFM insulator transition and a second anomaly in $D(T)$ near 250 K (300 K) which we assign to the transition to paramagnetism. The low-temperature anomaly can be a step of up to five times in the heat conductivity, which makes these compounds potential magnetic field activated heat switches, as this transition can also be induced by a magnetic field. © 1998 American Institute of Physics. [S0021-8979(98)44811-4]

I. INTRODUCTION

The magnetic and transport properties of $\text{RE}_{1-x}\text{EA}_x\text{MnO}_{3-\delta}$ compounds close to $x=1/3$ and $x=1/2$ are very sensitive to oxygen stoichiometry, way of preparation, annealing procedure, and atmosphere. In this contribution, we concentrate on the discussion of heat conductivity κ of Nd–Sr and La–Ca samples close to $x=1/3$, but of different make. Here, too, we observe a strong dependence on preparational conditions. As for example the oxygen content and interfacial stresses are difficult to determine with epitaxial layers, while with ceramics, defects and grain boundaries are often unspecified, we use a secondary characterization via other structure sensitive properties, e.g., electrical resistivity and magnetization. This way, at least a rough classification of the samples and a correlation of the different physical quantities can be achieved.

II. SAMPLE PREPARATION AND EXPERIMENT

The epitaxial thin films of thickness of $150\text{ nm} < d < 500\text{ nm}$ were deposited on SrTiO_3 substrates by laser ablation of polycrystalline targets. Substrate temperatures between 600 and 900 °C were used at a deposition pressure of 0.4 mbar oxygen. The x-ray diffraction patterns showed no other reflections than those consistent with a cubic unit cell. More details are given in the figure captions.

The “bulk” Nd–Sr sample is prepared by conventional solid state reaction. Stoichiometric proportions of high purity

starting materials, Nd_2O_3 , SrCO_3 , MnO_2 , are weighed and wet mixed for two hours in a planetary mill. The slurry is dried and further calcined in a recrystallized alumina crucible at 1200 °C for 24 h in air with three intermediate dry mixing/milling (carbide jar and ball) steps. Subsequently, the powder is cooled to room temperature, finely ground in a vibromill, and uniaxially pressed to pellets. The pellets are then sintered at 1500 °C for 5 h, cooled to 1300 °C at a rate of 30 K/h, and held there for 15 h. After that, it was cooled to room temperature at a rate of 120 K/h. X-ray powder diffraction confirmed a single phase with a pseudocubic structure ($a_0=3.852\text{ Å}$). The composition was tested using wet chemical analysis (ICP technique) and the weight in composition was confirmed within 3%. The “ceramic” sample, prepared from oxides and carbonates as above, was reacted in air at 1300 °C for several days with intermediate grindings. Pellets were pressed from the powders, sintered in air at 1250 °C for 10 h and cooled slowly to room temperature. The annealing procedure was repeated once. The x-ray peaks could be fitted to a cubic structure with lattice parameter $a_0=3.854\text{ Å}$.

The experimental setup used and the data reduction procedure is described in detail elsewhere.^{1,2} In order to measure κ we have chosen the transient thermoelectric effect (TTE), which primarily measures the heat diffusivity D , however, once D is known, the thermal conductivity κ can be calculated using specific heat capacity data, as $c_p \approx c_v$, $D = \kappa / c_v \rho_0$ (ρ_0 : density). We try to characterize each sample by its δ value and measurements of several physical quantities, taken on the same sample. Generally, with increasing δ both the magnetic moment and the conductivity are reduced.¹⁻⁶ From that, the oxygen content can be estimated; this has been done here by comparing the shifts and resistivity peaks obtained for different substrate temperatures of

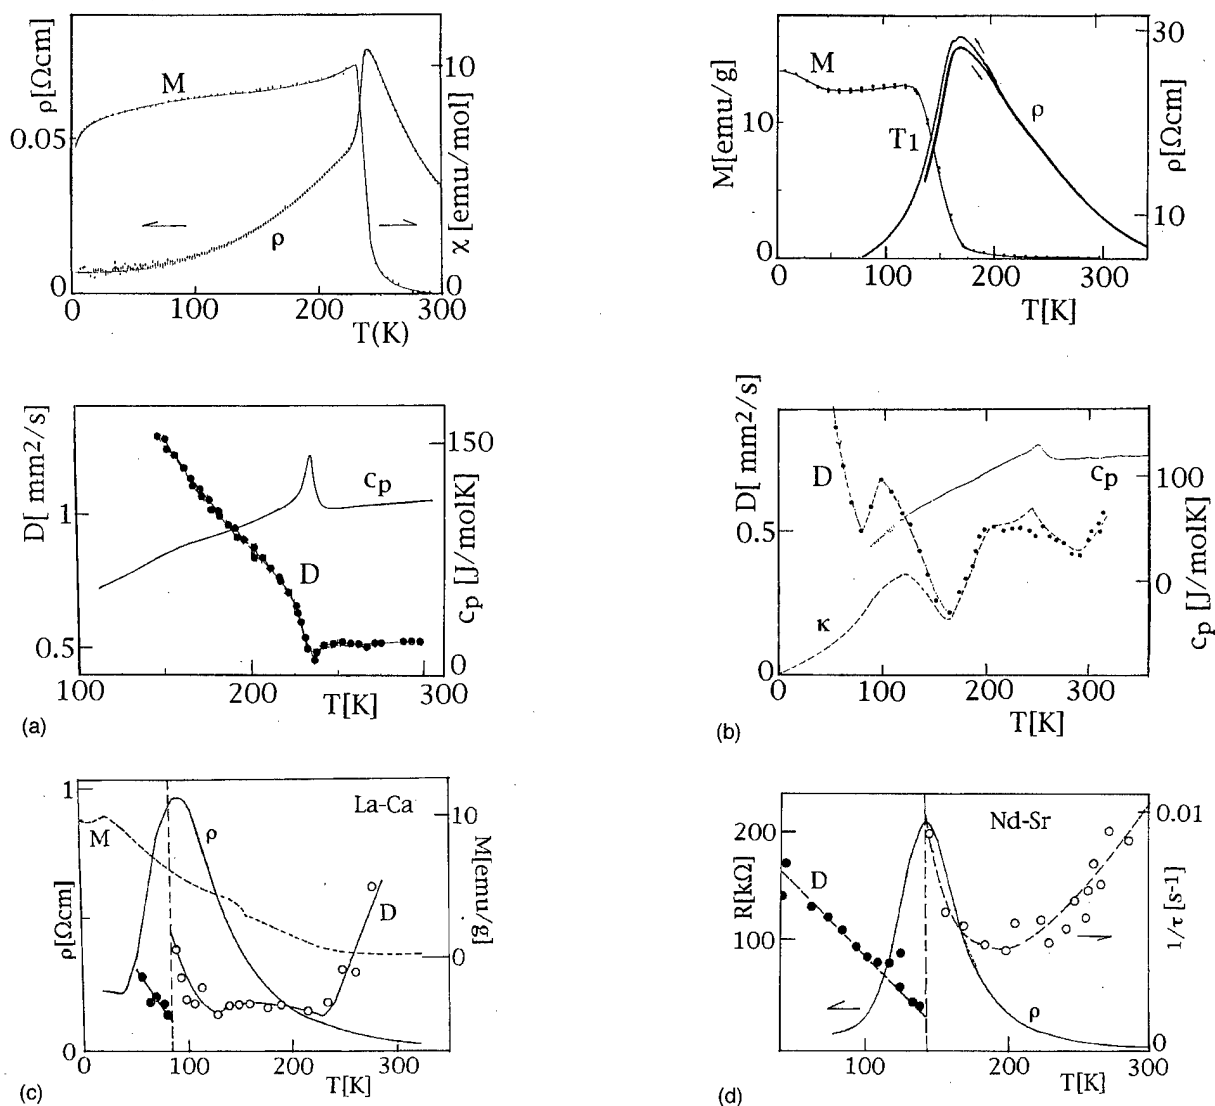

FIG. 1. Heat diffusivity D , specific heat capacity c_p , resistivity ρ , and magnetic moment M at $B = 100$ G of two bulk samples of $\text{RE}_{0.67}\text{EA}_{0.33}\text{MnO}_{3-\delta}$ vs temperature. (a) Bulk Nd-Sr $\delta \leq 0.04$, (b) ceramic Nd-Sr, $\delta \leq 0.14$. (c) Two epitaxial samples: laser ablation, SrTiO_3 substrate, 0.4 mbar O_2 Nd-Sr: $\delta \leq 0.1$, $T_s = 600^\circ\text{C}$, thickness: $d \approx 500$ nm and La-Ca: $\delta \leq 0.13$, $T_s = 800^\circ\text{C}$, $d \leq 150$ nm.

oxygen deficient Nd-Sr epitaxial layers⁷ with those of oxygen deficient La-Ca epitaxial layers and both of these with results obtained on oxygen deficient La-Ba ceramic samples, whose oxygen content had been chemically determined.⁶ Generally, an increasing oxygen deficit δ shifts all transitions to lower temperatures and simultaneously increases the spin randomness.¹⁻⁷

III. RESULTS

The magnetization of sample 1 is too low for collinear Mn-based ferromagnetism; therefore, $M(T)$ shows a canted order-disorder transition ($T_c = 240$ K). The spin disorder for $T > T_c$ could be paramagnetism or spin-glass like. The low resistivity for $T < T_c$ shows the correlation between metallic conductivity and (canted) ferromagnetism. The shape of $\rho(T)$ for $T < T_c$ suggests spin disorder scattering in particular, while activated behavior, i.e., a Mott or Arrhenius law is observed for $T > T_c$, suggesting a gap opening at T_c . The

heat diffusivity curve, $D(T)$, also shows T_c as a dip, while the low value of D for $T > T_c$, $0.5 \text{ mm}^2 \text{ s}^{-1}$, indeed suggests spin disorder.

While for sample 1 long-range magnetic order is introduced at 240 K, sample 2 shows a significant rise of magnetic moment $M(T)$ only at 150 K, which is again accompanied by a sharp drop in resistivity and is tentatively designated T_1 . The specific heat capacity $c_p(T)$, however, shows a peak around 240 K, suggesting a spin-compensated but mainly coherent magnetic structure for $150 \text{ K} < T < 240$ K and an incoherent, i.e., thermal or topological spin random structure for $T > 240$ K. The resistivity versus temperature curve $\rho(T)$ shows a weak shoulder at 240 K, suggesting a convoluted (double) resistivity peak and with it two different activated regimes. The absolute values of D and κ are comparable to those found for $\text{LaMnO}_{3-\delta}$.⁸ The dip in D close to 300 K could mark a final transition to paramagnetism, while the low value of D again suggests spin randomness. Close to T_1 , a peak of D is observed (see also Ref. 2). The epitaxial layers, samples 3 and 4, both show a broad

FIG. 2. Tentative phase diagram and placement of the samples 1–4; temperature scale might be slightly different for each sample.

resistivity peak like sample 2 which thus also might be a convolution. A step up to a factor of 5 is observed close to T_1 , which is accompanied by a sign change of the thermoelectric power in both cases; filled and open circles are used to demonstrate this. Again we observe the lowest value of D in the intermediate regime, $150\text{ K} < T < 250\text{ K}$. As the magnetic moment of La–Ca [Fig. 1(c)] is rather low, spin disorder is suggested, like in sample 2.

IV. DISCUSSION

The strong correlation of transport and magnetization is generally ascribed to the double exchange mechanism: here, metallic conductivity should occur together with ferromagnetisms through spindependent transfer of the extra electrons of the valence mixture. This correlation is indeed observed very often. The large variety of phenomena like GMR, field-induced metal-insulator transitions, mixed valence ordering, etc. are thought to occur mainly because of a competition of this double exchange mechanism and conventional superexchange of comparable strength, while a (spin) random component may be introduced through the oxygen deficit. In addition, large magnetovolume effects occur⁴ and point to a strong mutual influence between lattice and spin system, e.g., the idea of a rigid lattice has to be abandoned in general and polarons and Jahn–Teller like effects should be found. Although a phase diagram resulting from the competitive exchange has only been considered in connection with a rigid lattice and band filling scheme by deGennes, for an overview this diagram (Fig. 2) is still suitable. However, to the original diagram a few modifications have to be added:

- (1) The quadrupel point should be split by some additional (spin-orbit) interaction.
- (2) The randomness of the system introduces a percolation threshold for the conduction at which the carrier concentration is finite, x_p ; this is simultaneously a metal-insulator ($m-i$) boundary.
- (3) The paramagnetic region might be split into a spin-glass-like and a pm state because of the random elements.
- (4) The antiferromagnetic and paramagnetic phases might be insulating for $x > x_p^5$; i.e., the $m-i$ boundary runs probably first along T_1 and then along T_c .
- (5) Instead of a fixed carrier concentration as independent variable one should use the original ξ variable, i.e., the

ratio of maximal double exchange and superexchange energies $\xi = bx/|J|S^2$.

This way pressure effects and mechanical strains can be implemented to first order through the distance dependences of the transfer and exchange integrals $b(r)$, $J(r)$. If we tentatively place our samples 1–4 into that diagram, we assume that with increasing δ we have increasing nonstoichiometry hole doping and simultaneously an increase of spin randomness.^{1–5}

Figure 1 shows several anomalies in D and κ . First, with broad resistivity peaks one always finds a peak or a step close to the transition between the low-temperature metallic state and the high-temperature activated (semiconducting) region (at T_1). For magnetic materials, the heat conductivity is usually written as a sum of three terms,⁹ $\kappa = \kappa_{ph} + \kappa_{el} + \kappa_m$. As there are no structural changes in this temperature region, the phonon part κ_{ph} should be constant through this transition, while both the electronic κ_{el} and magnetic parts κ_m might be subject to change. This would also mean a higher sum $\kappa_{el} + \kappa_m$ in the thermally activated states. The flat region of the $\kappa(T)$ dependence for La–Ca and $T > 100\text{ K}$ might be due to blocked heat conduction in a spin-glass-like state and thus the increase in κ at higher temperatures, $T \geq 350\text{ K}$, could be connected with the onset of the paramagnetic regime.¹⁰

Magnetization measurements have shown that while stoichiometric $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ is a double exchange ferromagnet, oxygen deficient samples, e.g., $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3-\delta}$, $0 < \delta \leq 0.3$ are more complicated. At lower δ values and close to T_c a spin-polaron peak is often superimposed to the spin disorder scattering.⁵ However, with high $\delta > 0.1$ a change in character, i.e., an order-order transition has been proposed.^{1–5} In particular, a whole sequence of different magnetically ordered phases with decreasing temperature, i.e., paramagnetic (pm), spin glass like (sg), antiferromagnetic (afm), and canted has been proposed.^{1–5}

The valence state of Mn in magnetoresistive perovskites has been widely related to the level of alkaline metal substitution of the rare earth, by assuming that the Mn exists in 3+ or 4+ valence states. Measurements have been made on a series of samples in the system Pr_{1-(x+y)}Ca_xSr_yMnO₃. ⁵⁵Mn nuclear magnetic resonance (NMR) zero field spin echo measurements on a single crystal with $x=0.1$ and $y=0$ show distinct resonances around 310 MHz (Mn⁴⁺) and 400 MHz (Mn³⁺) but also at 590 MHz (Mn²⁺). An increase in the Mn²⁺ resonance frequency in an applied field implies that the Mn²⁺ moment is antiferromagnetically coupled to the net magnetization. Spectra from powder samples are much broader. The resonance frequencies increase as the Pr content is reduced. For systems with $x+y=0.4$, there is little change in the NMR spectrum as the proportions of Ca and Sr are altered. © 1998 American Institute of Physics. [S0021-8979(98)26511-X]

In recent years the large family of magnetic materials known as perovskites have been the subject of intensive research. They exhibit properties such as high temperature superconductivity and extremely high magnetoresistance.^{1-3,8} The renewed interest follows theoretical and experimental studies dating back to the 1950's.⁴⁻⁷

The cubic crystal structure of simple perovskites is distorted orthorhombically for many systems, such as Pr_{1-x}Ca_xMnO₃. It is the distorted perovskite manganese oxides of the form R³⁺A²⁺MnO₃ which exhibit the large negative magnetoresistance.⁸ The magnetoresistive response is thought to arise from the relationship between the level of A²⁺ dopant and the Mn valence affecting carrier mobility. The carriers hop preferentially between ions with a parallel spin configuration, stabilizing ferromagnetism (FM). The valence state v of the Mn ^{v +} has been widely related to the concentration x of the dopant by the formula

$$R_{1-x}^{3+}A_x^{2+}Mn_{1-x}^{3+}Mn_x^{4+}O_3^{2-}.$$

Transport measurements¹ made across a wide range of temperatures, however, indicate that there is some disproportionation of the 3+ state into 2+ and 4+ states. Here we present spin echo nuclear magnetic resonance (NMR) data on Pr_{1-(x+y)}Ca_xSr_yMnO₃. For $x=0.4$ and $y>0.1$, the system has the characteristics of a ferromagnetic conductor,³ as described below. The system was studied using an automated swept frequency spectrometer,⁹ in two regimes:

The first regime, $y=0$, exhibits² a number of different antiferromagnetic (AFM) structures for $x>0.5$, and mixed ferromagnetic (FM) and AFM characteristics for $x<0.5$. It is found to remain insulating for all compositions, though for $x=0.3$ a metamagnetic transition to a ferromagnetic conduc-

tor has been observed.¹⁰ At 4.2 K both the Mn and Pr sublattices are magnetically ordered. In this investigation the most detailed measurements have been made from 1.7 to 15 K on a single crystal with $x=0.1$ and $y=0$ in fields from 0 to 8 T. For this system the Curie temperature is 100 K, with a spin reorientation at around 70 K. The Pr sublattice orders at around 30 K, and the low temperature structure consists of moments FM coupled in plane with AFM coupling between planes.

In the second regime the total dopant level, $x+y$, is kept at 0.4 for a range of x and y . It has been found that despite the constant level of alkaline earth doping, there are changes in the magnetic properties of the system at 4.2 K as x/y is varied.³ For $y=0$, the system is AFM at low temperatures ($T_N=170$ K), but the introduction of Sr results in a mixed AFM/FM magnetic system. Above $y=0.1$ the material shows FM behavior with a decrease of resistivity, suggesting an increase in the stability of the ferromagnetic state.³ The magnetic and electronic properties are related to lattice distortions, introduced by a combination of size mismatch of the alkaline earth atom and the Jahn-Teller effect, with FM becoming increasingly dominant as the proportion of the Sr is increased.

NMR measurements were made on two samples with composition Pr_{0.9}Ca_{0.1}MnO₃; sample A was a single crystal produced by the floating zone method, using an infrared image furnace. The quality of crystals produced by this method is detailed by Balakrishnan *et al.*¹¹ Sample B was a powder produced, as described by Lees *et al.*¹²

The ⁵⁵Mn NMR zero field spin-echo spectrum of sample A in Fig. 1 shows three distinct resonances around 310, 400, and 590 MHz. These data have been obtained at 4.2 K in a carefully tuned and matched coil, and have been corrected for transverse relaxation (T_2) and the frequency squared signal dependence. No change in the resonant frequencies was observed in the range 1.7 to 15 K, but the drop in the relax-

FIG. 1. ^{55}Mn NMR spin-echo spectrum of $\text{Pr}_{0.9}\text{Ca}_{0.1}\text{MnO}_3$ single crystal at 4.2 K. Measurements are corrected for transverse relaxation effects and the "frequency squared" response effect.

ation time T_2 of the signals with temperature meant that no data were obtainable above 15 K.

The lines around 310 and 400 MHz were ascribed to Mn^{4+} and Mn^{3+} , respectively. The ^{55}Mn NMR resonance at 590 MHz is commonly ascribed to Mn in its $2+$ valence state and has been observed in a number of related systems such as spinel-type oxides¹³ and manganese ferrites,¹⁴ though it is interesting that no Mn^{2+} is observed in the La based perovskites by photoemission studies.¹⁵

The NMR data provide the first direct evidence for the presence of Mn in the $2+$ valence state in the $\text{R}^{3+}\text{A}^{2+}\text{MnO}_3$ systems, though indirect evidence of the inadequacy of the nominal $3+/4+$ valence approach has been obtained from thermoelectric power measurements across a wide range of temperatures.¹ Although it has been shown that layered manganese systems containing only Mn^{2+} and Mn^{3+} can be prepared, these have only been formed under highly reducing conditions.¹⁶ Since our data were obtained from a single crystal it is unlikely that the Mn^{2+} signal arises from any such spurious phase, though the large size difference may make Mn^{2+} difficult to accommodate in the lattice, and its association with lattice defects or an impurity phase cannot be ruled out. However, it should be noted that a large Mn^{2+} signal is not exhibited in the powder systems, as detailed below. Furthermore, the crystal was checked with x-ray Laue back reflection, which showed clear diffraction spots comparable to those shown in earlier work.¹¹

The data obtained at 4.2 K show that the apparent populations of the magnetically ordered Mn states, as detected by NMR are in the ratio 0.545:0.45:0.005 for the $4+$, $3+$, and

FIG. 2. ^{55}Mn NMR spin echo spectrum of $\text{Pr}_{0.9}\text{Ca}_{0.1}\text{MnO}_3$ single crystal at 2.75 K, with a range of applied fields.

$2+$ states, respectively. The nominal valence model would give an expected ratio of 0.1:0.9:0. The discrepancy is indicative of a large NMR enhancement of the Mn^{4+} signal, which may be due to domain wall enhancement arising from a preferential pinning of domain walls at the neighboring Ca dopant sites or may reflect the electron hopping dynamics. The rapid drop of the intensity of the Mn^{4+} line with applied field, as shown in Fig. 2, is consistent with removal of domain wall enhancement effects. The greater spread of hyperfine fields for the Mn^{3+} resonance compared with that of the Mn^{4+} line, shown in Fig. 2, is consistent with the presence of Jahn-Teller distortion about the Mn^{3+} ion.^{6,8}

FIG. 3. ^{55}Mn NMR spin echo spectra at 4.2 K of Mn^{4+} for $\text{Pr}_{1-(x+y)}\text{Ca}_x\text{Sr}_y\text{MnO}_3$ with $y=0$ for (a) single crystal $x=0.1$, (b) powder $x=0.1$, (c) powder $x=0.2$, and (d) spectrum of Mn^{4+} for $\text{Pr}_{0.6}\text{Ca}_{0.3}\text{Sr}_{0.1}\text{MnO}_3$ powder.

FIG. 4. Low intensity part of ^{55}Mn NMR spin echo spectra at 4.2 K for $\text{Pr}_{1-(x+y)}\text{Ca}_x\text{Sr}_y\text{MnO}_3$ with $x+y=0.4$ for (a) $y=0.1$, (b) $y=0.2$, (c) $y=0.3$, and (d) $y=0.4$.

A single $\text{Mn}^{3+}/\text{Mn}^{4+}$ mixed-state line at around 380 MHz has been observed in a range of other systems.¹⁷ This line arises from fast carrier hopping between the two Mn ions and therefore provides information about the ferromagnetic double-exchange mechanism. The absence of this line for $\text{Pr}_{0.9}\text{Ca}_{0.1}\text{MnO}_3$ suggests that if a double-exchange process is responsible for the ferromagnetism in this system, the hopping time must be greater than the period of the Larmor precession of the Mn nuclear spins ($\sim 10^{-9}$ s). The unusual absence of this line is consistent with the low conductivity of the ferromagnetic ground state, and suggests that the ferromagnetic ordering of the Pr sublattice ($T_c = 30$ K) may play a role in determining the low temperature magnetic structure of this system.

In Fig. 2, it can be seen that the resonance frequencies of the Mn^{3+} and the Mn^{4+} decrease with applied field, whereas the resonance frequency of the Mn^{2+} increases. Mn^{2+} is an S-state ion, so the hyperfine field at the nucleus is dominated by the contact interaction due to the host electron spin, i.e., the hyperfine field is antiparallel to the Mn^{2+} moment. The increase in the Mn^{2+} resonance frequency in an applied field implies that the Mn^{2+} moment is antiferromagnetically coupled to the net magnetization.

Figure 3 shows the Mn^{4+} spectrum, (a) from single crystal sample A, (b) from the powder sample B, and (c) from a powder sample $\text{Pr}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$. A powder sample of

$\text{Pr}_{0.6}\text{Ca}_{0.3}\text{Sr}_{0.1}\text{MnO}_3$, in Fig. 3(d) is also shown for comparison. It can be seen that the peak frequency of samples A and B is similar, though the line B is broader because of the greater inhomogeneity in the powder system. We were unable to detect any clear higher frequency resonance peaks from these powder samples, presumably because of this increased inhomogeneity. The shift in the peak indicates an increase in the magnitude of the field at the Mn nucleus as the Pr concentration is decreased, and may reflect an increase in mobility of the double exchange carrier between the Mn^{3+} and Mn^{4+} sites. The peak positions for the $\text{Pr}_{1-(x+y)}\text{Ca}_x\text{Sr}_y\text{MnO}_3$ samples with $x+y=0.4$, produced as described by Lees *et al.*,³ Figs. 3(d) and 4, are all around 380 MHz. This corresponds to an increase in the magnitude of the hyperfine field of about 3 T. As described above, the 380 MHz signal can be ascribed to a mixed $\text{Mn}^{3+}/\text{Mn}^{4+}$ state where the carrier hopping time is shorter than $\sim 10^{-9}$ s.

Despite the changes in the physical properties of $\text{Pr}_{1-(x+y)}\text{Ca}_x\text{Sr}_y\text{MnO}_3$ observed by Lees *et al.*,³ there is little change in the spectrum as the proportions of Ca and Sr are changed. Figure 4 shows the positions of the resonance lines for the Sr doped samples. Small peaks are observable at around 430 and 620 MHz, and are most well defined for the sample with the lowest Sr doping. The signals are extremely broad compared with the single crystal sample, and a distinct spin echo signal was observable across the whole range of frequencies shown in Fig. 4.

The magnetic behavior of bulk $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ ($T_C=267$ K) at low fields in the paramagnetic phase was studied. Near T_C ($T-T_C<30$ K) we find a sequence of steplike features in the effective Curie constant $C(T)=M(T-T_C)/H$ at well defined temperatures and intermediate plateaus, accompanied by temperature hysteresis. On approaching T_C , the C values at each plateau follow a geometrical progression, with the effective spin S doubled at each step. The first plateau gives $S=5.5$, corresponding to a cluster of three Mn^{3+} ions sharing one extra hole. This suggests that close to T_C short range magnetic order at low fields develops hierarchically through a series of most stable cluster states. © 1998 American Institute of Physics. [S0021-8979(98)52311-0]

I. INTRODUCTION

The doped manganites $\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$ (where Ln and A are trivalent lanthanide and divalent alkali-earth, respectively) are of great interest now due to the colossal magnetoresistance effect (CMR).¹ Although the basic mechanism for the onset of uniform ferromagnetism, the Zener's double exchange (DE) interaction, was recognized long ago,² it does not provide a satisfactory description of the magnetic state close to the transition temperature T_C .³ It was already noted in the previous authors' work⁴ that certain features observed in the critical behavior of MR disagree with the classical concept of electron spin scattering by thermodynamic fluctuations of localized Mn spins. A possible explanation was proposed through coexistence of thermodynamic and static fluctuations, the latter being due to spontaneous formation of spin clusters by local DE in the random potential of chaotically distributed dopants. Also it was evidenced⁵ that in these materials the magnetization per manganese atom $M(T)$ at higher temperatures T (up to about three times T_C) and applied field H does not follow the classical Curie-Weiss law $M_{\text{CW}}=C\mu_B^2 H/k_B(T-T_C)$. In particular, the apparent Curie constant (for $T-T_C$ up to ~ 100 K), obtained from the data of Ref. 5 on $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$, is $C\approx 11.4$, much higher than the simple weighted sum $\bar{C}=xC_{3/2}+(1-x)C_2$ of Brillouin contributions $C_S=4/3S(S+1)$ from Mn^{4+} ($S=3/2$) and Mn^{3+} ($S=2$); for $x=1/3$ we have $\bar{C}=7$. There is a general

consensus about the relation of this effect to the formation of composite cluster spins,^{6,7} for instance, a spin-coupled pair of Mn^{4+} and Mn^{3+} will contribute $C_{7/2}=21$ which is ≈ 1.6 times greater than the sum $C_{3/2}+C_2$ for two uncoupled spins, and such enhancement must be even stronger for greater clusters. The same data show that at sufficiently high temperatures the Curie-Weiss law with $C\approx\bar{C}$ is restored (but with modified $T'_C>T_C$). This suggests that cluster formation is favored closer to the transition temperature. But, like the usual ferromagnetic transition, a strong enough external field will suppress the critical spin fluctuations and spontaneous cluster structure can be smeared. In the present work we study the deviations from uniform paramagnetic behavior of $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ with approaching T_C , at as low applied fields as possible. Besides confirming the difference between the Curie constants close and far from T_C at fields ranging above some kOe, we found some essentially new effects close to T_C at fields below ~ 50 Oe. Particularly, a sequence of steplike features observed at well-defined temperatures and accompanied by temperature hysteresis suggests a discontinuous dynamics of spin clustering with possible hierarchical structure.

II. EXPERIMENT

A bulk ceramic sample of composition $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ was prepared by standard solid-state methods from oxides and carbonates, with three intermediate grindings and final sintering at 1300°C for 50 h and very slow cooling to room

^{a)}Electronic mail: vbamaral@fc.up.pt

FIG. 1. $(dM/dT)^{-1/2}$ from high temperature measurements at field 8 kOe. The arrow indicates the orthorhombic-trigonal structural transition at $T_{O-T} \approx 750$ K.

FIG. 2. Inverse magnetization close to T_C . Instead of a continuous decrease, we find a sequence of steps and intermediate regions where a Curie-like type of dependence seems valid (lines).

temperature within 20 h. Powder diffraction showed a single phase orthorhombic structure (P_{bnm}), and scanning electron microscopy revealed that the samples have very small porosity and 10 μm average grain size. High resolution electrical resistivity and magnetoresistance measurements confirmed the characteristic behavior of these ferromagnetic ceramics.⁸

The low field magnetization of the sample was measured with a Quantum Design superconducting quantum interference device (SQUID) magnetometer. In order to reduce the effect of frozen magnetic fields in the superconducting coil and ensure a better field homogeneity, prior to these measurements the coil was heated to room temperature. During the measurement of these low field data, the maximum magnetic field did not exceed 30 Oe. The measurements at constant magnetic field were taken on cooling the sample from high temperatures (320–380 K), down to 20 K and then on heating back to the initial temperature. On the first run, at 1.36 Oe, a zero-field cooled curve was also measured. High temperature (300–1000 K) magnetic measurements were taken in an Oxford Instruments vibrating sample magnetometer (VSM) with a constant applied field of 8 kOe.

III. RESULTS AND DISCUSSION

Well above T_C where the sample magnetization $M(T)$ is small, we separated the paramagnetic term from the diamagnetic background by means of the derivative dM/dT to evaluate the function $1/\sqrt{dM/dT}$. For $M=M_{CW}$ it should be linear in temperature: $(T-T_C)/\mu_B\sqrt{CH/k_B}$, but from our measurements up to 1000 K this function is slightly nonlinear (Fig. 1). Hence, either C or T_C (or both) are not exactly constants, and therefore the effective cluster spin $S_{\text{eff}} = 3C/4\bar{S} - 1$ (note that C is defined per one Mn spin, and the mean spin value $\bar{S} = x3/2 + (1-x)2 = 11/6$ provides $C\bar{S} \approx \bar{C}$) and its coupling to neighbor spins (clusters) $J_{\text{eff}} \approx 4T_C/C$ are temperature dependent. We found the experimental value of the Curie “function” $C(T)$ to increase from $\approx \bar{C}$ at $T > 800$ K to ≈ 14.8 at 300–350 K (from the two linear asymptotes far and close to T_C), in agreement with known data.^{6–8} The same $C(T)$ value at 300 K is obtained with SQUID and VSM measurements. The hump at the orthorhombic-trigonal structural transition $T_{O-T} \approx 750$ K

(shown in Fig. 1), can be explained by the increase of exchange at shrinking lattice parameters. To our knowledge, this is the first report of the $O-T$ transition through magnetic measurements. Resistivity measurements showing a kink at T_{O-T} were reported in literature.⁹

To understand the high-temperature behavior of $C(T)$, we calculated the spectrum of spin states for the simplest cluster model of two Mn^{3+} atoms, sharing one extra hole with hopping amplitude t . Apart from the splitting between bonding and antibonding states, known already from the semiclassical approach,² the spectrum is characterized by equal separation $t/4$ between levels which is not exactly equivalent to isotropic Heisenberg exchange. With decreasing temperature the calculated Curie function rapidly grows from the asymptotic value $C_{3/2} + C_{3/2} + C_{1/2}$, for fully independent components, to the limit $C_{7/2}$ for the fully aligned cluster spin.

Closer to T_C , where the diamagnetic contribution can be neglected, $C(T)$ can be defined directly as $M k_B (T - T_C)/\mu_B^2 H$ where $T_C = 263.5$ K fits best. For magnetic fields above 50 Oe, $C(T)$ displays even faster growth, which can be associated with a rapid continuous increase of effective cluster spin S_{eff} . Similar behavior for $(\text{La}_{1-x}\text{Tb}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ was already reported.¹⁰ In addition to this, in lowest fields (< 50 Oe) some discrete steplike features appear in the magnetization data. In Fig. 2 we show the inverse magnetization as a function of temperature. It is seen that between steps a Curie-like behavior is observed (lines). The Curie function $C(T)$ is represented in Fig. 3 for several fields. Here these anomalies are more clear, with steps at well-defined temperatures and intermediate plateaus, and lower is the field better resolved are these features. This effect is new and it shows that intrinsic short range magnetic order in the considered material develops through a series of more or less stable intermediate states (clusters). We plotted the logarithms of plateau heights of $C(T)$ at different fixed fields and found them to grow almost linearly with the plateau number ($n=0,1,2,\dots$) (Fig. 4). The case $n=0$ is taken as the limiting value for independent spins measured at high temperatures: $\log C_{\text{step}}(n) \approx \log \bar{C} + \gamma n$, with $\gamma \approx \log(2.1 \pm 0.1)$. This can be interpreted as if the typical cluster spin S_{eff} is doubled each time as the corresponding temperature

FIG. 3. Steplike behavior of the Curie function at low magnetic fields close to T_C . Inset: Temperature irreversibility effects.

T_n is reached. The first plateau around $T_1 \approx 290$ K with $C_1 \approx 15$ relates to $S_{\text{eff}} \approx 5.5$, which fits to a cluster of three Mn^{3+} ions sharing one extra hole, in coherence with the stoichiometric $\text{Mn}^{3+}/\text{Mn}^{4+}$ ratio. The consecutive plateaus around $T_2 \approx 280$ K, $T_3 \approx 276$ K, $T_4 \approx 269$ K, and $T_5 \approx 266$ K (observed in fields down to 0.5 Oe) can correspond to condensation of clusters with $S_{\text{eff}} \approx 11, 22, 44, 88$.

It is noteworthy that neither the temperature intervals between the steps nor their stability against the applied field are equal. For instance, the feature at $T_3 \approx 276$ K (supposedly 12 Mn^{3+} ions coupled by four extra holes) looks particularly stable. Also a considerable temperature hysteresis of magnetization $M(T)$, confined just to the range of steplike behav-

FIG. 4. Approximate linearity of logarithms of the plateau C values vs plateau number, indicating that these follow a geometrical progression, with the effective spin S doubled each time as a step occurs. The point for plateau 0 is obtained at high temperatures.

ior, suggests that the steps can be compared to a series of first kind phase transitions in the spin subsystem (inset to Fig. 3).

The sequence of cluster states for this sample can consist of: a triplet of Mn^{3+} ions sharing one extra hole, in line, six Mn^{3+} ions sharing two extra holes, possibly in a 2×3 rectangle, twelve Mn^{3+} ions sharing three extra holes possibly in a $2 \times 2 \times 3$ parallelepiped (two cubes) and so on. The calculation of the lowest energy level for clusters in a cubic lattice containing three Mn^{3+} ions for each hole in the double exchange Hamiltonian gives the following values: $E/t = -1.41, -1.71, -1.89, -2.06, -2.08$, and -2.20 for the cases of 1, 2, 3, 4, 6, and 9 holes in a cluster. Some of these values were recently reported by Gehring and Coombes.¹¹ It can be seen that the formation of clusters with more than four holes (12 ions) does not lead to a considerable energy reduction, while loosing in entropy. This may serve as an explanation for the above-indicated stability of the feature at $T_3 \approx 276$ K.

For comparison, the same measurements were also done on a less doped sample of $\text{La}_{0.75}\text{Ca}_{0.25}\text{MnO}_3$. Here the effect of strong enhancement of the Curie constant and hysteresis at low fields are also observed close to the transition temperature ≈ 232 K, however, no clear fine structure was seen even at lowest fields.

Low field magnetotransport in $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films

B. S. Teo,^{a)} N. D. Mathur, S. P. Isaac, J. E. Evetts, and M. G. Blamire

Department of Materials Science, University of Cambridge, Pembroke Street, Cambridge CB2 3QZ, United Kingdom

We have observed a strong correlation between the degree of epitaxy and the low field resistance versus field $R(H)$ behavior in highly textured $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films grown by pulsed laser deposition on SrTiO_3 substrates. Highly epitaxial films show a small temperature dependent low field hysteretic $R(H)$ peak near the magnetic ordering temperature (T_c), when the applied field is parallel to the transport current ($J\parallel H$). In contrast, films with reduced epitaxy show a much larger low field hysteretic $R(H)$ behavior with a pronounced in-plane angular dependence. The magnitude of this response grows with decreasing temperature below T_c . Our data and analysis suggest that even low angle grain boundaries play a fundamental role in transport properties in colossal magnetoresistive materials. © 1998 American Institute of Physics. [S0021-8979(98)26611-4]

I. INTRODUCTION

In recent years, much effort has concentrated on understanding the magnetotransport properties of alkaline earth substituted perovskite manganese oxide $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ ($\text{A}=\text{Ba}, \text{Sr}, \text{Ca}, \text{Pb}$, or vacancies).^{1,2} These doped lanthanum manganites with a perovskite structure exhibiting colossal magnetoresistance (CMR) in the vicinity of the ferromagnetic ordering temperature (T_c) with a large applied magnetic field of the order of few Tesla. More recently, there have been a number of reports of a sensitive low field response in polycrystalline materials,^{3,4} heterostructures,⁵ and artificial grain boundaries.⁶ Resistance as a function of applied field [$R(H)$] plots for these systems share the common features of a hysteretic low field peak structure, which is reminiscent of metallic spin valve or spin tunnel devices. It has been noted recently that similar, though smaller, low field peaks can also be observed in epitaxial thin films near the ferromagnetic ordering temperature T_c .⁷

In this article, we report the results of careful measurements on batches of films with varying degrees of epitaxy. At low temperatures, we observe an angular and field dependent resistance hysteresis in the samples with the lowest degree of epitaxy. This behavior is absent in the films with higher crystalline order. We attribute the phenomenon to the low angle grain boundaries in the material. We demonstrate that a recently developed model for grain boundary behavior is consistent with the results.

II. EXPERIMENTAL DETAILS

$\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (LSMO) thin films were grown on (001) SrTiO_3 (STO) substrates by pulsed laser deposition at growth temperatures between 900 and 600 °C in an oxygen ambient of 15 Pa, and annealed *in situ* at the growth temperature in 50 kPa of oxygen for 1 h. All films showed a single (001) growth direction and texture scans showed that in each case the film was aligned with the substrate crystal axes. X-ray rocking curves (θ scans) showed that films grown above

700 °C (designated type I films) had a full width at half maximum (FWHM) of 0.2–0.5°. In contrast, a broad FWHM of $\approx 2^\circ$ was shown by the films grown at 600 °C (type II), indicating a significantly lower crystalline quality, implying the presence of a high density of low angle grain boundaries. The magnetization of the films was measured against temperature and field using a vibrating sample magnetometer (VSM) at temperatures down to 77 K. The low field transport properties of the samples were measured as a function of temperature, magnetic field, and in-plane angle between transport current and the applied magnetic field (θ) using a standard four-point probe. The contacts to the film were made using spring-loaded “pogo” pins without patterning the sample so that subsequent magnetization measurement could be made to obtain meaningful comparisons of electrical and magnetic properties.

III. RESULTS

$R(H)$ measurements of type II films (Fig. 1) show a large resistance hysteresis which is especially pronounced at low temperature, and diminishes as the temperature increases towards T_c . At higher fields, these samples show a highly linear variation of resistance with applied field which is a characteristic feature of data from both polycrystalline samples,⁴ and artificial grain boundaries.⁶ The large negative magnetoresistance (MR) [defined as $\text{MR}=(R_{\text{res}}-R_{\text{max}})/R_{\text{max}}$, where R_{max} is the maximum resistance and R_{res} is the resistance at $H=0$ extrapolated from high field slope] decreases as temperature increases. By comparison type I films showed a small resistance hysteresis only near T_c . At 77 K, not only is the absolute resistance two orders of magnitude lower than for type II films, but the samples display an extremely small positive MR when $J\perp H$ ($\theta=90^\circ$) as opposed to a negative MR in the $\theta=0$ configuration (see inset to Fig. 1).

We show in Fig. 2 the angular dependence of the resistance for type II films as a function of θ at various applied fields at 77 K, as measured during a series of field sweeps. While the resistances measured at $H=0$ and $H=H_c$ do not show a significant angular dependence, at an applied field of

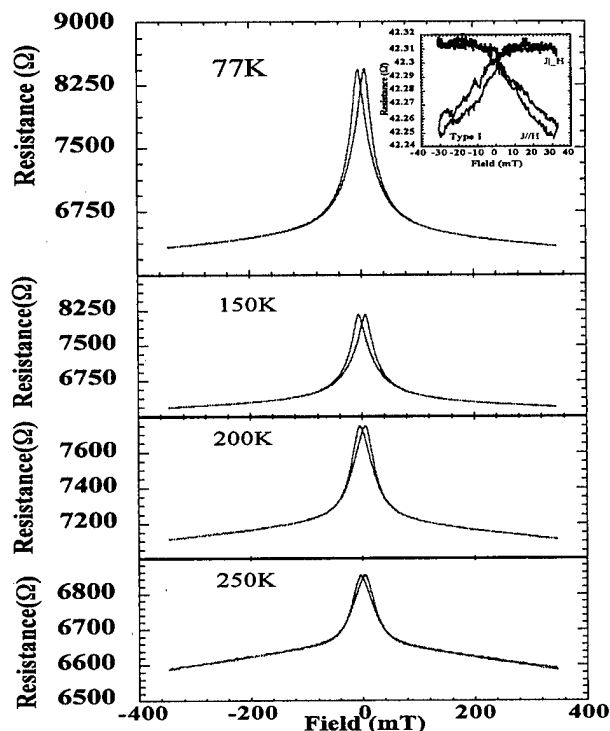

FIG. 1. Resistance (R) vs in-plane applied field (H) at a series of temperatures for type II films. Inset shows the corresponding $R(H)$ curve with the current parallel and perpendicular to the applied field for a type I film at 77 K.

50 or 250 mT the resistance gradually increases with θ , reaching a maximum at 90° before decreasing back to a minimum at 180° . We have confirmed that this is not a simple demagnetization effect caused by the shape of the chip by repeating the measurement with the current at 90° to the original direction.

Figure 3 shows the in-plane magnetization loop for both types I and II samples. The high field magnetization of the type II sample is both lower than in the case of the type I sample, and less square. This data appears to contradict that of Gupta *et al.*³ in which the high field magnetization for polycrystalline samples was found to be higher than for epitaxial films. However, in our measurements the high field

FIG. 3. Magnetic hysteresis loops measured at room temperature for types I and II films.

differential susceptibility for the type II material is higher than it is for the type I samples which is consistent with a reduced magnetic order associated with the grain boundaries.

IV. DISCUSSION

The possibility that the low field MR can be an intrinsic effect due to domain wall scattering can be ruled out, since single crystal materials (like our type I samples) show an MR which vanishes as the temperature tends to zero. The finite MR at low temperature shown by type II samples is similar to that for truly polycrystalline films reported by Li *et al.*⁸ and Steenbeck *et al.*,⁹ and the linear high field response is similar to that reported by Hwang *et al.*⁴ The implication is therefore that even low angle grain boundaries can dramatically modify the transport properties of the CMR manganites. In our previous studies of bicrystal grain boundary devices,⁶ a phenomenological model¹⁰ based on the existence of a region of depressed magnetic order induced by grain boundary was proposed to explain both the high field and the low field MR behavior. In this model the low temperature MR behavior in isolated grain boundaries is attributed to structural disorder and strain at the grain boundaries, thus depressing the local magnetic order and so greatly reducing carrier mobility.

Direct evidence for a reduction in magnetic order in type II samples is provided by the measured difference in the magnetization data between the two film types; the lowest high field magnetization is measured in the type II samples which contain the highest proportion of grain boundary material. This confirms that the spontaneous magnetization in the grain boundary regions is lower than it is within grains. The reduced squareness of the magnetization loop taken for the type II sample is consistent with the onset of the high field regime occurring at higher fields than it does during measurements of the type I samples. This finding is consistent with the existence of a magnetocrystalline anisotropy which has been reported to play a measurable role at low fields.⁷

The main result of the model described in Ref. 10 is that the magnetoresistance of polycrystalline films can be approximated as

$$\Delta R_{gb}/R_0 = -\gamma(M_0^2 + 2M_0\chi_{gb}fM_e + 2M_0\chi_{gb}H), \quad (1)$$

TABLE I. Summary of the data for a type II sample at four different measurement temperatures. R_{90} and R_0 are the resistance of the films for $\theta=90^\circ$ and 0° , respectively, dR/dH is the high field change in resistance with applied field, M_e is the magnetization deduced from Eq. (1) used the analysis in the text, and M_{spont} is the measured magnetization of the same film.

Temperature (K)	$R_{90}(\Omega)$	$R_0(\Omega)$	$R_{\text{max}}(\Omega)$	$dR/dH(\Omega \text{ mT}^{-1})$	M_e	$M_{\text{spont}}(\text{mT})$
77	6275	6173	8163	0.670	152	148
150	7014	6937	8062	0.517	149	140
200	7161	7111	7751	0.357	140	124
250	6654	6630	6893	0.239	100	113
300	5530	5523	5603	0.132	53	81

where M_e is the saturation magnetization of the intragranular material, f is the fraction of M_e applied to the grain boundary region (usually, but not necessarily the cosine of the angle between the direction of M_e and the normal to the grain boundary), M_0 is the spontaneous grain boundary magnetization, and χ_{gb} is the differential susceptibility of the grain boundary. This model correctly predicts the linear high field magnetoresistance observed in both artificial grain boundary devices and polycrystalline material (see Fig. 1).

The angular dependence observed in Fig. 3 is accounted for in this model by the variable f . In our films we expect a range of grain boundary orientations to be present; however, it is only grain boundaries which lie perpendicular to the current flow which are likely to contribute significantly to the resistivity, and consequently we can replace the angle between the induced magnetization and the normal to the significant grain boundaries $\arccos(f)$ by the angle between the current and field (θ). The inset of Fig. 2 shows that a plot of R at fixed field versus $\cos(\theta)$ is linear as predicted by Eq. (1).

On the basis that $f=\cos(\theta)$, the difference in MR between the $\theta=0^\circ$ and 90° field configurations should be equal to $2\gamma M_0 \chi_{\text{gb}} M_e$. The ratio between this quantity and the high field slope (dR/dH) should then be equal to M_e . Table I shows data obtained from a type II film at a number of temperatures. The excellent agreement between the measured magnetization and that inferred from the model provides considerable support for this model.

V. CONCLUSIONS

The results presented here demonstrate that even highly textured CMR thin films can have magnetotransport proper-

ties which are identical to fully polycrystalline samples. This highlights the significance of low angle grain boundaries in manganite perovskites, and places strict requirements for the growth of ideal CMR material on nonideal substrates. More positively, it demonstrates that control of the sample microstructure allows the development of technologically desirable low field properties in simple single layer films.

Magnetostriction $\lambda_{||}(H)$ and field-induced phase transitions were studied in the single crystal of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0, 0.05, 0.1$, and 0.175) in the pulsed magnetic fields up to 230 kOe. Anomalies in the $\lambda_{||}(H)$ curves were revealed at 200 kOe in the LaMnO_3 , which were identified with the spin-reorientation $A_yF_z \rightarrow A_zF_y$ in the magnetic field $H \parallel b$ axis. A complicated magnetostriction behavior was observed in $\text{La}_{0.875}\text{Sr}_{0.125}\text{MnO}_3$, related to the field-induced transition between orthorhombic and rhombohedral crystal structures. © 1998 American Institute of Physics. [S0021-8979(98)47011-7]

Lanthanum manganites doped by the divalent ions Sr (Ca) attract a considerable recent attention due to an observation of various interesting phenomena such as a giant negative magnetoresistance, magnetic, structural and metal-insulator phase transitions, a charge ordering.¹⁻⁴ Various field induced magnetic and structural phase transitions are expected in these compounds. Magnetostriction may serve as a sensitive indicator of the change of magnetic and crystal structures. The recent finding of the field induced structural phase transition in $\text{La}_{0.83}\text{Sr}_{0.17}\text{MnO}_3$ ^{3,5} indicates a strong coupling between the magnetic and crystal subsystems in these compounds. In this article we report on the magnetoelastic properties and field induced transitions in $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ in pulsed magnetic fields.

Single crystals of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0, 0.05, 0.1$, and 0.175) were grown by the floating zone method with radiation heating in an air atmosphere. X-ray powder diffraction measurements showed that grown crystals were of single phase; however, they had a twin structure.

The magnetostriction was measured by a quartz sensor, stuck on the samples, in pulsed magnetic fields up to 230 kOe at temperatures of 10–300 K. Magnetization $M(T, H)$, ac magnetic susceptibility $\chi_{ac}(T)$ and resistance $\rho(T)$ measurements were performed in the static magnetic fields $H \leq 12$ kOe at $T=4.2$ –300 K.

LaMnO_3 : It is known that $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ manganites have a distorted perovskite crystal structure, which undergoes a structural phase transition between a low-temperature orthorhombic phase and a high-temperature rhombohedral one.^{2,3,5,6} In the pure LaMnO_3 Mn^{3+} spins are ordered antiferromagnetically at $T_N \approx 140$ K along b axis of the orthorhombic $Pbmn$ crystal and a small spin canting takes place along c axis (magnetic layer structure of the A_yF_z type).⁷⁻⁹

Our magnetic measurements have shown that there are four easy directions of a spontaneous magnetic moment in

the studied LaMnO_3 crystals due to an existence of the twin structure in the samples. The easy axes lie approximately in the (110) and (1-10) planes of the orthorhombic crystal. There are six types of the twins with c axis along the $\langle 100 \rangle$ directions corresponding to the high temperature cubic cell.⁹ Estimated values of the spontaneous magnetic moment and transverse susceptibility for the nontwin crystal at $T=78$ K are $m_0 = 4.2 \pm 0.5$ emu/g and $\chi_{\perp} = (1.8 \pm 0.3) 10^{-4}$ cm³/g, respectively.

The measurements of the longitudinal magnetostriction $\lambda_{||}$ were carried out in the magnetic field H oriented along the b axis in one of the twins. The example of the $\lambda_{||}(H)$ curve for LaMnO_3 at $T=29$ K is shown in Fig. 1, where the apparent jump is observed at $H \sim 200$ kOe on the background of the smooth increasing of the magnetostriction. We identified this anomaly with the spin-reorientation phase transition from A_yF_z to A_zF_y magnetic configuration induced by the $H \parallel b$ axis in one of the twins. Recently an anomaly in the magnetization behavior of the LaMnO_3 was observed near the same magnetic field ($H \approx 210$ kOe) applied along b axis.¹⁰ The threshold field H_c of this transition may be determined analogously, to the corresponding transitions in orthoferrites:¹¹

$$H_c = -H_D + (H_D^2 + 2H_A H_E)^{1/2}, \quad (1)$$

where $H_E = M_0/2\chi_{\perp} \approx 330$ kOe, $H_D = m_0/\chi_{\perp} \approx 23$ kOe (at $T=78$ K) are the isotropic and antisymmetric exchange fields, respectively, $H_A = K_{cb}/M_0$ is the effective anisotropy field in the bc plane and K_{cb} is the corresponding anisotropy constant, $M_0/2$ is the sublattice magnetization. Using the value of the antiferromagnetic resonance frequency for LaMnO_3 ^{9,12} $\hbar\omega = g\mu_B(2H_A H_E)^{1/2} \approx 17$ –19 cm⁻¹ at the $T < 50$ K, where μ_B is the Bohr magneton and $g \approx 2$ is a g tensor, we have estimated H_c as 180–200 kOe that is in good agreement with our experiment. We note the small contribu-

FIG. 1. Magnetic field dependence of the magnetostriction in LaMnO_3 and $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$.

tion of the antisymmetric exchange to the threshold field $H_c[H_D \ll (2H_A H_E)^{1/2}]$ allows to consider the observed spin reorientation as a simple spin-flop transition.

$\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$: In the case of small substitutions of the La^{3+} ions by the Sr^{2+} the magnetic structure remains of the $A_y F_z$ type is evidenced by neutron scattering and magnetic study of the $\text{La}_{0.96}\text{Sr}_{0.04}\text{MnO}_3$.¹³ Our study of the practically nontwin single crystal of the $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ confirms this conclusion. The corresponding magnetization curves presented in Fig. 2 show that the spontaneous magnetic moment is along the c axis, the magnetic susceptibilities along a and c axes are practically equal to each other

FIG. 2. Magnetization curves in $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ along different crystallographic axes ($T=4.2$ K).

FIG. 3. Magnetic field dependence of the magnetostriction in $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$.

and determine the transverse susceptibility ($\chi_a \approx \chi_c = \chi_\perp$), and the susceptibility along b axis, determined by the rotation susceptibility ($\chi_b \approx \chi_{\text{rot}} = m_0^2 / K_{cb}$), is much greater than $\chi_{a,c}$. The large value of the χ_{rot} is consistent with the noticeable increase (about 4 times) of the canting angle and decrease of the anisotropy constant K_{cb} as compare with the pure LaMnO_3 . It implies also the decrease of the threshold field induced the spin-reorientation $A_y F_z \rightarrow A_z F_y$, whose value is estimated as 35 kOe using Eq. (1).

However, our measurements of the longitudinal magnetostriction along b axis $\lambda_\parallel \equiv \lambda_{bb}$ in the $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ (Fig. 1) do not exhibit any anomaly in the $\lambda_\parallel(H)$ curve near of the expected threshold magnetic field (~ 35 kOe) besides a weak bend observed at 100–150 kOe. The absence of the apparent anomaly in the $\lambda_\parallel(H)$ curve of the $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ may be due to a smooth character of the $A_y F_z \rightarrow A_z F_y$ spin reorientation which occurs through the angular $A_y A_z F_z F_y$ phase in contrast to the practically abrupt transition in pure LaMnO_3 . In this case we cannot exclude a more crucial role of the twin structure in a mask of the smooth spin reorientation in the $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ sample, destined for the magnetostriction measurements.

$\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$: For the $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$ composition, which already exhibits the ferromagnetic ordering ($T_C \approx 165$ – 170 K), we observed unusual behavior of the longitudinal magnetostriction near T_C (Fig. 3). The magnetostriction had no anomalies at the low temperatures (10–130 K) and reached only the saturation value about $(2-3) \times 10^{-5}$. However, a weak jump aroused near 50 kOe at $T=139$ K, which was transformed at 150 K to the strong anomaly near 80 kOe accompanied by increasing the magnetostriction up to one order of the magnitude. With the further temperature increasing, the magnetostriction changed a sign in the weak

FIG. 4. Temperature dependence of the magnetization in $\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$ at $H = 160$ Oe.

magnetic fields, but the positive jump in the higher field remained up to T_C despite its amplitude being reduced (see curves at 160 and 166 K at Fig. 3).

Such complicated behavior of the magnetostriction near T_C may be associated with field induced magnetic and structural phase transitions. According to the neutron scattering studies^{14,15} an antiferromagnetic ordering as well as a structural transition related to a polaron ordering takes place in $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$ below T_C which implies a possibility of the magnetic field effect on these transitions.

$\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$: The strong effect of magnetic field on the phase transitions between orthorhombic and rhombohedral crystal structures was observed in the $\text{La}_{0.83}\text{Sr}_{0.17}\text{MnO}_3$, where the structural transition temperature T_S , close to T_C , was decreased from 280 K at $H = 0$ down to 220 K at $H = 70$ kOe.^{3,5} However, in the case of $x = 0.16$ and 0.18 the T_S 's remained almost unchanged since there was a considerable difference between corresponding T_S and T_C .⁵ The mechanism of the transition is connected with a lower value of the magnetization in the orthorhombic phase than in the rhombohedral one.

We studied the composition with $x = 0.175$, where, according to our magnetic measurements (Fig. 4), $T_C \approx 285$ and $T_S \approx 160$ –190 K. Figure 5 shows the dependence of the longitudinal magnetostriction versus the magnetic field at several temperatures. At the low temperatures ($T < 182$ K) the magnetostriction behaved in ordinary manner without anomalies (curve at 150 K), while near the T_S the magnetostriction increased rapidly after reaching a threshold value (curves at 182 and 194 K), which we identify with field-induced structural transition. We note the strong hysteretic phenomena accompanying the transition, so that the crystal does not remain in the initial state after removing the magnetic field. We cannot exclude additional relaxation effects in the related phenomena considering the measurements in the pulsed magnetic fields.

FIG. 5. Magnetic field dependence of the magnetostriction in $\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$.

In conclusion, we have studied the magnetostriction in $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ in the strong pulsed magnetic fields and demonstrated its sensitivity to the field induced spin reorientation and structural phase transition, observed in LaMnO_3 and $\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$, respectively.

We present magnetic-, resistivity-, and specific-heat measurements of the title compounds and found that in $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ an insulator-metal transition can be induced by an external field below 60 K while $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ remains insulating. EuMnO_3 exhibits two magnetic transitions at 35 and 47 K which are associated with the appearance of a weak ferromagnetic component and antiferromagnetic ordering. With respect to the parent compound, Ca and Sr substitution enhance the ferromagnetic component significantly, however, for low fields and after zero-field cooling the antiferromagnetic ground state is preserved to a large extent. © 1998 American Institute of Physics. I. INTRODUCTION

Rare earth manganite perovskites $\text{R}_{1-x}\text{A}_x\text{MnO}_{3+\delta}$ ($\text{R}=\text{rare earth elements}, \text{A}=\text{Ca}, \text{Sr}, \text{Ba}, \text{Pb}$) show colossal magnetoresistance and attracted renewed attention not only due to their potential applications but also because of their rich physical properties (for a review see, e.g., Ramirez¹ and references therein). Since most of the works were devoted to La and Pr based manganites it is the aim of this article to study the properties of $\text{Eu}_{0.7}\text{A}_{0.3}\text{MnO}_3$ where Eu is suggested to be trivalent and thus exhibits a nonmagnetic groundstate ($J=0$) and a smaller ionic radius than La^{+3} .

II. EXPERIMENTAL DETAILS AND STRUCTURAL CHARACTERIZATION

Ceramic samples of the title compounds were synthesized from Eu_2O_3 , MnO_2 , SrCO_3 and CaCO_3 of high purity by sintering at temperatures 900–1100 °C for 24 h. The resulting powders were reground and annealed in air at 1300 °C for 12 h. As follows from x-ray analysis the samples have distorted perovskite structure and contained less than 5% impurity phases. Resistivity was measured by four-point technique by a Keithley-182 nanovoltmeter with 10 G Ω input impedance; contacts were made by ultrasonic soldering

with indium. ac susceptibility and dc magnetization were measured by a conventional lock-in technique and by a superconducting quantum interferometer device (SQUID) magnetometer, respectively. Heat capacity measurements were carried out by a quasiadiabatic step heating technique in fields up to 11 T. The valence state of Eu ions at room temperature was estimated by x-ray photoelectron spectroscopy (XPS) using the ESCALAB-5 electron spectrometer and twin anode Al/Mg source. Clean surfaces of EuMnO_3 were obtained by cleavage *in situ* in UHV and/or by ion bombardment. Electronic structure and binding energies of the Eu 4*f* spectra of EuMnO_3 were compared with divalent and trivalent oxides of Eu and found to be very close to the trivalent oxide Eu_2O_3 . The lattice parameters and structural data are collected in Table I.

III. RESULTS AND DISCUSSION

Shown in Fig. 1(a), *b* is the specific heat and ac susceptibility of EuMnO_3 and the substituted compounds. For the parent EuMnO_3 compound both measurements exhibit a double peak at 47 and 35 K. The former corresponds to the antiferromagnetic (AF) ordering while the anomaly at 35 K is attributed to the evolution of a weak ferromagnetic (FM) component which we derive from the dc magnetization at various external fields in Fig. 2. For clarity we present in

TABLE I. The structures and lattice parameters of the title compounds. The error is given in brackets.

	Structure	<i>a</i> (Å)	<i>b</i> (Å)	<i>c</i> (Å)	γ	<i>V</i> (Å ³)
EuMnO_3	Orthorhombic	5.336(2)	5.833(2)	7.456(3)	90.0	232.1(3)

FIG. 1. The specific heat, C_p/T vs T , (a) and the real part of the ac susceptibility in a semilogarithmic scale (b) of EuMnO_3 , $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$, and $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$.

Fig. 2 only the magnetization measurement after zero-field cooling (ZFC) for $\mu_0 H \geq 0.1$ T but both the field cooled (FC) and ZFC magnetization for 10 mT. The AF ordering temperature is in agreement with the early report on EuMnO_3 by Pauthenet and Veyret² (45 K) and that of Troyanchuk *et al.*³ for $\text{EuMnO}_{3.02}$ (40 K) who also showed that with growing oxygen deficiency T_N moves to higher temperatures. In the dc magnetization T_N is not as clearly seen as in the specific heat and ac susceptibility data but coincides with the disappearance of the irreversibility between the ZFC and FC

FIG. 2. The temperature-dependent magnetization of EuMnO_3 measured after zero-field cooling (ZFC) for $\mu_0 H \geq 0.1$ T and both the field cooled (FC) and ZFC magnetization data for 10 mT.

FIG. 3. The temperature-dependent magnetization of $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ measured after zero-field cooling (ZFC) for $\mu_0 H \geq 0.1$ T and both the field cooled (FC) and ZFC magnetization data for 10 mT.

branch of the magnetization. The occurrence of a weak FM component is associated with a thermal hysteresis of the field cooled magnetization for cooling and warming. In the ZFC magnetization a maximum occurs at 35 K which is broadened and washed out with growing external fields. This is consistent with the specific heat data where the AF ordering temperature remains nearly unchanged while the 35 K anomaly is washed out and entropy is transferred to higher temperatures as the external field is raised. Furthermore a metamagnetic transition into a weak FM state is observed at about 3 T at 2 K concomitant with the occurrence of a remanent magnetization of about 3 Am²/kg after a linear decrease of $M(H)$ from a value of 11.9 Am²/kg at 6 T. This together with the above findings indicates a more complex AF ordering than in LaMnO_3 where FM sheets are coupled antiferromagnetically. Nevertheless, we assume for EuMnO_3 basically a similar AF coupling since in the low temperature specific heat a dominant T^2 term is present over a wide temperature range and is clearly seen as the linear temperature dependence in the C_p/T versus T plot in Fig. 1(a). The heat capacity of EuMnO_3 can well be described in the temperature regime from 2 to 20 K with the Debye function (yielding a Debye temperature $\Theta_D = 470$ K) and a T^2 term with a coefficient of 10 mJ/mol K⁴ but without the necessity to include a γT term. The T^2 term is also observed in the layered antiferromagnet LaMnO_3 and is supposed to arise from a linear and quadratic spin wave dispersion corresponding to linear AF and planar FM excitations.⁴

For the Sr and Ca substituted samples a FM contribution, which is far from the full Mn moment, dominates the magnetization process but for low fields and for zero-field cooling the AF coupling is preserved to a large extent. As shown in Fig. 3 the shape of the $M(T)$ curves for ZFC and FC is similar to that of the parent compound. However, the “spontaneous moment” extrapolated from high fields of the Arrott plots in Fig. 4 is 1.45 $\mu_B/\text{f.u.}$ (1.55 $\mu_B/\text{f.u.}$) and the moment at 6 T and 2 K amounts to 2.17 $\mu_B/\text{f.u.}$ (2.7 $\mu_B/\text{f.u.}$) for $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ ($\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$). A metamagnetic transition is clearly visible in the Arrott plot for 2 K at a field of 0.2 T which is reduced with rising temperatures. Both the

FIG. 4. Isothermal magnetization measurements on $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ for various temperatures displayed as Arrott plot, M^2 vs $\mu_0 H/M$.

small value of the ZFC magnetization in low fields and the metamagnetic transition provide strong indication of the basically AF ground state of the Sr and Ca doped compounds with $x=0.3$ at low fields. The FM ordering temperature deduced from the high field regime of the Arrott plot is 74 and 62 K for $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ and $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$, respectively. Note the low field data of the isotherm at 60 K indicate already paramagnetism although a hysteresis opens at higher fields yielding a small but finite remanent magnetization. T_C of the Sr doped sample coincides with the maximum of the ac susceptibility (63 K) while for the Ca doped sample the shoulder of $\chi_{ac}(T)$ at about 75 K can be correlated with T_C but a maximum of $\chi_{ac}(T)$ occurs at significantly lower temperatures (47 K). While the absence of a specific heat anomaly at T_C remains unresolved for the Ca and Sr substituted samples the significant change of the low temperature heat capacity is obvious. A broad Schottky anomaly which presumably arises from higher multiplets of Eu^{+3} makes it impossible to disentangle the lattice contribution from a possibly small γT term, however, the dominant spin-wave T^2 term of the parent compound is diminished upon Ca or Sr substitution. The appearance of a broad Schottky term is in line with an increase of the effective moment deduced from the high temperature susceptibility: EuMnO_3 $\mu_{\text{eff}} = 5.3 \mu_B/\text{f.u.}$; $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ $\mu_{\text{eff}} = 5.9 \mu_B/\text{f.u.}$; $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ $\mu_{\text{eff}} = 6.8 \mu_B/\text{f.u.}$

FIG. 5. The resistivity, $\rho(T)$, of $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ for various fields as labeled.

Both the Ca and Sr doped samples remain insulating in zero-field down to 50 K where the resistance exceeds the value to be measured with the present set up. However, with an external field the metal insulator transition can be induced for $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ below 60 K (see Fig. 5) while for $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ a field of 11 T is not sufficient to induce the metallic state. This is in line with the magnetic data showing that even the doped compounds with $x=0.3$ exhibit basically an AF ground state and ferromagnetism can be induced by an external field. Thus, these samples fit to the general phase diagram proposed by Hwang *et al.*⁵ where $\text{Eu}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ is situated on the verge of the FM insulator to a FM metal while $\text{Eu}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ with the smaller tolerance factor remains insulating.

Magnetization and resistivity of CrO₂ powders and oriented CrO₂ films on different TiO₂ single-crystal substrates are reported, and the low-temperature specific heat is measured on powders. The $M(T)$ data follow a Bloch $T^{3/2}$ law, with no sign of a spin-wave gap. The residual resistivity depends strongly on film texture, but a T^2 temperature dependence of the resistivity is found in all samples above a cut-off temperature of the order of 70 K. The behavior is attributed to electron-magnon spin-flip scattering which is suppressed at low temperature in a half-metallic ferromagnet. © 1998 American Institute of Physics. [S0021-8979(98)44911-9]

I. INTRODUCTION

CrO₂ is a unique ferromagnet. It is a metallic oxide which crystallizes in the rutile (TiO₂) structure. The Cr ions, which are octahedrally coordinated by oxygen, have a formal 4+ valence state and an electronic configuration [Ar]3d². The two d electrons occupy spin split t_{2g} subbands. Numerous electronic band structure calculations predict "half-metallic" ferromagnetism with complete spin polarization of the 3d electrons at and below the Fermi level.¹⁻⁴ One t_{2g} ↑ electron is localized in a narrow xy band while the other is itinerant in a half-filled band of $yz+zx$ character. The Fermi level falls in a deep dip in the density of states at the center of this band; the empty ↓ states are ≈1 eV higher in energy.^{3,4} The tendency toward gap formation has been confirmed by photoemission measurements.⁵ The dip in the density of states in the middle of the half-filled band suggests that CrO₂ is close to a Mott-Hubbard transition. Like mixed-valence manganates having the perovskite structure, the ferromagnetic order of CrO₂ is mainly due to itinerant d electrons moving among localized ion cores⁴ ($S=1/2$ for CrO₂, $S=3/2$ for manganites).

Here we discuss magnetic, thermal, and transport properties of CrO₂ and present evidence for a gap in the excitation spectrum for spin-flip electron scattering.

II. EXPERIMENTAL METHODS AND RESULTS

CrO₂ films, 0.5–2 μm in thickness, have been prepared by the thermal decomposition of CrO₃ under high oxygen pressure onto oriented TiO₂ substrates.⁶ X-ray diffraction showed that the films are single phase, and grazing incidence diffraction indicated that they grow epitaxially. Atomic force microscopy (AFM) pictures reveal that CrO₂ films on TiO₂(100) and (110) have an acicular (needlelike) structure with grains of ≈50 μm length oriented with their axes in the plane of the substrate. On TiO₂(001), the textured CrO₂

films have the needle axis normal to the plane, resulting in the appearance of grains with circular cross sections of 1–5 μm in diameter (Fig. 1).

The resistivity of CrO₂ films having a (100), (110), or (001) texture have been measured in the temperature range 5–300 K using a four-probe technique. The results are shown in Fig. 2. The residual resistivity is quite different for the three samples. The film with its c axis perpendicular to the plane of the film has the highest residual resistivity, due to the greater number of grain boundaries compared to those films with their c axis in plane. The grain boundary resistivity for the (001) film is estimated from the size of the crystals (≈3 μm) to be $r_{gb} \approx 5 \times 10^{-10} \Omega \text{ m}^2$, which is similar to the value found in manganites.⁷ The (001) film shows a low-field magnetoresistance similar to that of CrO₂ powder compacts⁸ and two-phase films⁹ as well as polycrystalline manganite films¹⁰ and ceramics.¹¹ Consistent fits to the resistivity could not be obtained with a normal expression in powers of T that

FIG. 1. AFM pictures of CrO₂ films on TiO₂ (a) (100) and (b) (001).

FIG. 2. Resistivity curves for CrO₂ films grown on TiO₂(100), (110), and (001). The solid lines are the fits to Eq. (1).

was used in Ref. 6. Superior fits over the full range of temperature were obtained with

$$\rho(T) = \rho_0 + \alpha T^2 \exp(-\Delta/T), \quad (1)$$

parameters ρ_0 , α , and Δ are listed in Table I. At low temperatures, the films with few grain boundaries are fairly good metals, with a residual resistivity below 10 $\mu\Omega$ cm, which barely changes up to about 70 K. However, at room temperature and above, CrO₂ becomes a poor metal, with a resistivity that exceeds the Ioffe–Regel limit.^{3,12} A change in the slope of $\rho(T)$ occurs at T_c but the derivative $d\rho/dT$ remains positive.⁶

Magnetic measurements were carried out using extraction or vibrating sample magnetometers on commercial acicular powder and on a CrO₂ powder obtained by decomposing CrO₃ in a high-pressure reactor vessel. The latter contained Cr₂O₅ impurities. Arrott plots in the temperature range 300–520 K gave a Curie temperature of 396(6) K. The magnetization measured in a field of 1 T was found to follow the Bloch $T^{3/2}$ law (Fig. 3):

$$M(T) = M(0)(1 - BT^{3/2}), \quad (2)$$

with $B = 3.4 \times 10^{-5} \text{ K}^{-3/2}$. The spin-wave stiffness constant D estimated from B is approximately 150 meV \AA^2 .¹³ Any gap in the ferromagnetic dispersion relation is estimated from the data of Fig. 4 to be less than 5 K. Measurements of magnetocrystalline anisotropy¹⁴ show it is of the order of 0.1 K.

TABLE I. Parameters from fits of the resistivity of CrO₂ films to Eq. (1).

Resistivity	ρ_0 ($\mu\Omega$ m)	α ($\Omega \mu\text{K}^{-2}$)	Δ (K)
100	1.23	359×10^{-12}	73
110	0.07	41×10^{-12}	80
001	7.07	480×10^{-12}	73

FIG. 3. $M(T)$ for a CrO₂ powder showing $T^{3/2}$ behavior.

Specific heat as a function of temperature has been measured on the commercial powder in the range 2–40 K (Fig. 4). We fit the data below 15 K to the expression

$$C = \gamma T + \beta T^3 + \alpha T^{5/2}, \quad (3)$$

where the electronic specific heat coefficient $\gamma = 5.1(9) \text{ mJ/mol K}^2$ corresponds to a density of states at the Fermi level of 2.2 states/eV. This may be compared with a calculated value of 0.69 states/eV.³ The value of β , 0.028 mJ/mol K⁴, corresponds to a Debye temperature of 593 K. The third term is associated with spin-wave excitations. The value of α , 1.9 mJ/mol K^{5/2} corresponds to $D = 60 \text{ meV } \text{\AA}^2$.

FIG. 4. C/T vs T^2 for pressed CrO₂ powder. The solid line is the fit to Eq. (3).

III. DISCUSSION

At temperatures below about 100 K, we have seen that CrO_2 is intrinsically a fairly good metal, with a residual resistivity of a few $\mu\Omega$ cm. The films with resistivity considerably higher than this have a distinct granular structure. The value of the electronic specific heat coefficient γ is similar to that of iron (which has approximately two holes in the $3d$ band), but the difference between the density of states at the Fermi level inferred from γ and the value calculated by Lewis *et al.*³ shows that the effective mass in the oxide $m^* = 3.2 m$. The calculations also show that the Fermi surface area in CrO_2 is small, which is to be expected if it is just on the metallic side of the Mott transition.

It is remarkable to see how the good metal changes into a poor one on approaching T_c . The temperature dependence of the resistivity is characteristic of spin-disorder scattering. Although there are several other possible origins of a T^2 temperature dependence, electron-magnon scattering is the most likely in the present case since the compound is a ferromagnet. Electron-magnon scattering has recently been established as the dominant scattering process in ferromagnetic manganites.¹⁵ The ineffectiveness of the scattering mechanism below 100 K is not related to any gap in the magnon spectrum, since neither magnetization, specific heat, nor anisotropy show any evidence of a gap of this magnitude. It must, rather, be associated with the electronic structure of CrO_2 . Electron-magnon scattering is a spin-flip process, and spin-flip scattering is impossible at low temperature in a half-metallic ferromagnet because the nearest available \downarrow states to scatter into are well above the Fermi level.¹⁶ The problem is how to relate the spin-polarized density of states to spin disorder. In fact, spin polarization must persist on a local scale even at temperatures above T_c since the susceptibility follows a Curie-Weiss law.¹⁴ The relation $kT = Dq_T^2 = 4\pi^2 D/\lambda_T^2$ defines the minimum wavelength λ_T of magnons excited at a temperature T . The significance of the gap $\Delta = 80$ K may be that $\lambda_\Delta \approx 30 \text{ \AA}$ is the critical wavelength where spin-flip scattering becomes important. An electron which travels this distance finds \downarrow states available on sites where there is locally a maximum spin deviation associated with the spin wave, and it can therefore undergo a spin-flip scattering process there with absorption or emission of a magnon. The distance λ_Δ is determined by the nonspin-flip scattering processes. This concept is illustrated in Fig. 5.

The poor metal at room temperature and above, where the mean free path is comparable to the interatomic spacing, may be understood in terms of Mott-Hubbard localization in the half-metallic system. This arises when the bandwidth $W = 2zt < U$, where z is the coordination number, t the interatomic transfer integral, and U the on-site Coulomb repulsion. At temperatures near and above T_c , any site will have a fluctuating number z' of neighbors with reversed spins to

FIG. 5. Spin-flip scattering in a half-metallic ferromagnet is ineffective at temperatures where the nonspin-flip mean free path $\lambda_{\uparrow\uparrow}$ is less than the shortest magnon wavelength λ_T (left), but it is dominant when $\lambda_{\uparrow\uparrow} > \lambda_T$.

which transfer is forbidden, so the effective bandwidth is reduced by a factor $(z - z')/z$. Conduction is possible only when a local fluctuation of the spins of an atom relative to its neighbors to all parallel makes the system locally metallic. At any instant, the number of $3d$ electrons which are delocalized and available to conduct is reduced to a fraction of the number of sites. Since spin-disorder resistivity is inversely proportional to the electron density, values well in excess of the typical Ioffe-Regel limit, $150 \mu\Omega$ cm, can arise.

The effect of low Fe substitution in Mn sites of $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ is presented. We report the electrical and magnetic properties of these materials in the Fe concentration range $x=0$ to $x=0.1$. The metal-insulator transition temperature is found to vary significantly with very small Fe doping. The metal to insulator transition temperature increases slightly when a very small amount of Fe is doped ($<1\%$) and then it decreases significantly with further doping of Fe. The magnetic moment of $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ decreases almost linearly with Fe doping at room temperature. © 1998 American Institute of Physics. [S0021-8979(98)26811-3]

I. INTRODUCTION

Giant magnetoresistance (GMR) effect shown on the perovskite oxide materials has attracted a lot of research interest. The metal-insulating transition temperature (T_{tr}) is known to be dependent on the Mn–O–Mn bond angle and bond length. Double exchange^{1–3} has been used to explain qualitatively the transport phenomena as well the magnetic ordering observed in these perovskite oxides. The insulating material LaMnO_3 when doped with divalent ions such as Ca, Sr, Ba, Pb, etc. causes a conversion of proportional number of Mn^{3+} to Mn^{4+} . The electron hopping between the mixed Mn valence states then causes ferromagnetic ordering and metallic conduction in these systems.²

Up to date, much exploration of the GMR perovskite materials has been done through doping of La sites with rare earths (Y, Nd, Pr, etc.) of different sizes, which brings strong lattice effects thus influencing the double exchange.^{4,5} However, very few studies have been carried^{6–8} out to observe the effects of transition metal ion doping on Mn sites, which will bring out the changes in electronic structure thus influencing double exchange. Effect of large doping of Fe ($>10\%$) on $\text{La}_{0.8}\text{A}_x\text{MnO}_3$ (where $\text{A}=\text{Sr}, \text{Ca}, \text{Ba}, \text{Pb}$) systems and its magnetic ordering has been reported earlier by Banks *et al.*⁹ However, the effect of lower Fe doping ($<10\%$) has not been reported on a systematic study. In this article we report the effect of low Fe ($<10\%$) doping on Mn sites of $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ system.

II. EXPERIMENTAL DETAILS

The samples were prepared by the conventional solid state technique by taking Fe_2O_3 , MnCO_4 , SrCO_3 , and La_2O_3 in appropriate stoichiometric proportion as the starting material. These powders were milled and calcined at 900°C .

The calcined powder was remilled and the compacts were sintered at 1300°C in air for 6 h. The fired samples were characterized by x-ray diffraction, with $\alpha\text{-Al}_2\text{O}_3$ used as the internal standard. Resistivity studies were carried out on 2-mm-thick rectangular samples. Resistivity measurements were carried out for all the samples in the temperature range from 15 to 473 K by conventional four-probes method. In the range 15–300 K a closed cycle refrigerator was employed to cool the sample and for high temperature studies (room temperature to 473 K) a variable temperature oil bath was used. Room temperature magnetization studies were carried out by using a vibrating sample magnetometer (VSM) setup with a maximum field of 0.4 T.

III. RESULTS AND DISCUSSION

The x-ray diffraction (XRD) spectra of samples with extreme concentration of Fe ($x=0, 0.1$) are shown in Fig. 1. It is clearly seen from the figure that both the samples show similar XRD pattern. XRD spectra for all the other samples between these concentrations are also found to be similar. The XRD spectra were indexed by assuming a pseudocubic structure. The lattice constants were found to be 3.8790 and 3.8811 Å for $x=0$ and $x=0.1$, respectively. The studies of Fe doping on Ca containing LaMnO_3 systems ($>10\%$)⁷ also does not show any changes in the lattice parameter. Studies by Jian *et al.*⁸ also showed that the lattice parameter of $\text{La}_{0.67}\text{Ca}_{0.33}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$ remains nearly identical, i.e., 3.8571 Å for $x=0.0$ and 3.8561 Å for $x=0.1$. This indicates that the doping of Fe has hardly any influence on lattice parameter. This could be because of the identical ionic sizes¹⁰ of Fe^{3+} and Mn^{3+} .

In Fig. 2 the variation of normalized resistance with temperature is shown. All the samples show a metal-insulator transition temperature. At low temperature, for all the samples, the resistance curve tends to flatten out. Transition

FIG. 1. XRD spectra for the samples $\text{La}_{0.8}\text{Sr}_{0.2}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$ with $x=0$ and 0.1 .

temperature is found to be strongly dependent of the Fe doping even at low concentrations.

For the parent sample, i.e., $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ the transition temperature is found to be 350 K which is agreeing with the reported values for the Sr composition 0.2.¹¹ Transition temperature T_{tr} increases when doped with small amount of Fe (≈ 0.005) and then it decreases systematically with the addition of Fe content and for $x=0.1$, transition temperature was found to be ≈ 260 K. Recently Ahn *et al.*⁷ showed that in the Ca containing LaMnO_3 system both in the ferromagnetic as well as the antiferromagnetic region the transition temperature is varying with respect to the Fe doping ($>10\%$). In the ferromagnetic region transition temperature decreases with increase in Fe concentration. The decrease in the transition temperature with Fe doping could be due to the

FIG. 2. Temperature dependence of normalized resistance for Fe doped samples $\text{La}_{0.8}\text{Sr}_{0.2}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$, $0 < x < 0.1$.

FIG. 3. Variation of magnetic moment with different concentration of Fe in $\text{La}_{0.8}\text{Sr}_{0.2}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$, $0 < x < 0.1$.

replacement of Fe^{3+} on Mn^{3+} thus reducing the double exchange interaction.

Magnetization studies on these systems indicates the ferromagnetic nature of the samples. The variation of magnetic moment of the sample with Fe concentration at room temperature is shown in Fig. 3. With the Fe doping the magnetic moment of the sample decreases. The magnetic moment decreases almost linearly with the Fe doping. Magnetic moment decreased from 2.52 to $0.2 \mu_B$ for $x=0$ and $x=0.1$, respectively. In the case of Ca containing systems⁷ the decrease of magnetic moment is found to be from 3.2 to $2 \mu_B$ for $x=0$ to $x=0.1$ at 5 K.

IV. CONCLUSION

The lattice parameter of $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ does not change with Fe concentration. Metal-insulator transition temperature was found to increase at a very low concentration of Fe ($<1\%$) and decreases with further addition of Fe. Magnetic moment of the samples decreases sharply even at very low concentration of Fe.

Departamento de Química Inorgánica, Universidad del País Vasco/EHU, P.O. Box 644, E-48080 Bilbao, Spain

The magnetic and magnetoresistive properties of the $\text{Ln}_{0.7}\text{Pb}_{0.3}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$ ($\text{Ln}=\text{La}$, Nd , and $x=0, 0.1$) perovskites, prepared by the sol-gel low temperature method, have been studied. In all cases the exact stoichiometry is different from the nominal one probably due to the presence of cation vacancies. All the phases exhibit ferromagnetic behavior with T_c values ranging from 345 K observed for $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$ to 75 K for $\text{Nd}_{0.7}\text{Pb}_{0.3}\text{Mn}_{0.9}\text{Fe}_{0.1}\text{O}_3$. The 10% Fe contribution lowers the T_c by about 130 K in the La compound and 90 K in the Nd one. These results can be interpreted in terms of antiferromagnetic coupling between Mn and Fe. However, the influence of the Nd ions is not well known although it seems not ordered down to 10 K. The magnetoresistance [$\text{MR} = \Delta R/R(0)$] measured at 6 T in pellets of pressed powder reaches values of about 80% around the magnetic transition. © 1998 American Institute of Physics. I. INTRODUCTION

During the last years the hole-doped perovskite $\text{A}_{1-x}\text{A}'_x\text{MnO}_3$ type compounds ($\text{A}=\text{La}^{3+}$, Sm^{3+} , Pr^{3+} , Nd^{3+} , ..., $\text{A}'=\text{Ca}^{2+}$, Pb^{2+} , Sr^{2+} , Ba^{2+} , Cd^{2+}) have attracted the attention of scientific community due to the observation of colossal magnetoresistance (MR) phenomenon.¹⁻³ The magnetic behavior and transport properties of these samples are determined by several factors such as the percentage of the divalent ions, the ionic radii of the metal ions, the method used in the preparation of the samples, etc. The distortion of the perovskite structure has a direct influence not only on the Mn–O distance, but also on the angle of the $\text{Mn}^{3+}\text{–O–Mn}^{4+}$ bond. It has been also observed that ferromagnetic coupling and metal–insulator transition temperature are very sensitive to the change of these parameters.² On the other hand, the substitution of the Mn ions by other transition metal ions can give rise to important modifications in the magnetic and transport properties.⁴

In this work we report the magnetic and magnetoresistive properties of $\text{Ln}_{0.7}\text{Pb}_{0.3}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$ ($\text{Ln}=\text{La}$, Nd and $x=0, 0.1$), which have been prepared by the sol-gel low temperature method. This method presents the advantage of using low-temperature synthesis, that results not only in smaller grains but also produces high purity and homogeneous powders.⁵ We compare structural, magnetic, and magnetoresistance measurements with the aim to reach a better understanding of the effect caused by the presence of different lanthanide elements and the substitution of Mn by Fe ions in the samples.

II. EXPERIMENT

Mixed oxides of compositions $\text{Ln}_{0.7}\text{Pb}_{0.3}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$ ($\text{Ln}=\text{La}$, Nd and $x=0, 0.1$) were prepared by the sol-gel method with the required quantities of La_2O_3 , $\text{Pb}(\text{NO}_3)_2$,

$\text{Mn}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$, and $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ as starting materials. Citric acid and ethyleneglycol were used as gelling agents for the La and Mn ions in a nitrate solution. After drying in a sand bath, the obtained gel was subjected to successive heat treatments at different temperatures: 773, 973, and 1073 K, respectively, each of them for 10 h. The microcrystalline powder thus obtained was pelletized and sintered at 1173 K for 10 h in flowing oxygen. In the following, the prepared compounds will be labeled as LaPb, LaPbFe, NdPb, and NdPbFe.

The $\text{Mn}^{3+}/\text{Mn}^{4+}$ content of each sample was determined by redox titration using an excess of FeSO_4 (0.025 M) solution and back titration with 0.5 M permanganate. In all cases we observed a greater content of Mn^{4+} to that corresponding to the nominal composition (see Table I). These deviations from theoretical stoichiometries could be due to an excess in the oxygen concentration or more probably to the presence of cation vacancies.⁶

TABLE I. % Mn^{4+} , Goldschmidt's tolerance factor, t [$t=(r_A+r_O)/\sqrt{2}(r_B+r_O)$], and crystallographic data for the studied compounds.

Sample	% Mn^{4+}	t	Space group	Lattice parameters
$\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$	65	0.9915	$R\bar{3}c$	$a=b=5.514 \text{ \AA}$ $c=13.405 \text{ \AA}$ $\beta=119.99^\circ$
$\text{La}_{0.7}\text{Pb}_{0.3}\text{Mn}_{0.9}\text{Fe}_{0.1}\text{O}_3$	53	0.9915	$R\bar{3}c$	$a=b=5.519 \text{ \AA}$ $c=13.340 \text{ \AA}$ $\beta=119.97^\circ$
$\text{Nd}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$	56	0.9688	Pnma	$a=5.480 \text{ \AA}$ $b=7.720 \text{ \AA}$ $c=5.456 \text{ \AA}$
$\text{Nd}_{0.7}\text{Pb}_{0.3}\text{Mn}_{0.9}\text{Fe}_{0.1}\text{O}_3$	57	0.9688	Pnma	$a=5.484 \text{ \AA}$ $b=7.728 \text{ \AA}$ $c=5.467 \text{ \AA}$

X-ray diffractograms were recorded on a Philips X'PERT diffractometer using Cu K_α radiation. The space group and lattice parameters, determined by the Rietveld method using the FULLPROF program,⁷ are shown in Table I. The diffraction maxima of the La phases were indexed in a rhombohedral space group ($R\bar{3}c$) while Nd ones exhibit an orthorhombic symmetry (Pnma). This result is in good agreement with the higher distortion exhibited by the neodymium perovskitelike compounds. In this way, the Goldschmidt's tolerance factors t of these phases are lower than those obtained for the La compounds (see Table I). However, the t values are greater than 0.968 in all cases, hinting for a good stability of the structure.

Magnetic and resistance measurements were performed in a quantum design MPMS-7 superconducting quantum interference device magnetometer. The zero field cooling (ZFC) and field cooling (FC) curves were performed under an applied field of 8 kA/m. $M(T)$ curves at 1 T applied field and hysteresis loops at 10 K and up to 7 T were also obtained. The resistance and MR versus temperature measurements were carried out using a dc four-probe system with the current parallel to the applied field.

III. RESULTS AND DISCUSSION

The temperature dependence of the resistance measured under zero and 6 T applied fields for all samples is shown in Fig. 1. In absence of applied field a resistance maximum, characteristic of a semiconductor-metal transition, is observed. For the LaPb composition the transition temperature is $T_{SC-M} \approx 270$ K, which is into the range of values observed for La manganites doped with alkaline-earth ions (235–330 K).⁸ However, the change of La by Nd in the perovskite composition gives as a result a drastic decreasing in the value of this T_{SC-M} , being now ≈ 140 K. These transition temperatures decrease when adding Fe to the compositions (see Table II).

When applying a 6 T magnetic field the value of the resistance decreases in all the temperature range. In all samples a change in the MR behavior occurs around the semiconductor-metal transition temperature. The relative magnetoresistance defined as: $[R(6T) - R(0T)]/R(0T)$,⁹ is higher in the samples containing Fe, reaching values of around 65% and 80% for the La and Nd phases, respectively.

The magnetic behavior observed from ZFC and FC curves corresponds to a magnetic inhomogeneous system¹⁰ where ferromagnetic grains or clusters are embedded in a nonferromagnetic matrix. The ZFC and FC measurements have been carried out under applied field of 8 kA/m, lower than the value of coercivity measured at 10 K for all samples. The results are shown in Fig. 2. All compositions, except NdPbFe, show an extraordinary similarity, hinting for the same magnetization process at low applied field. The ZFC curves show a maximum at a given temperature and fall at higher temperature due to the ferro-paramagnetic transition. For temperatures below that maximum, the decrease in the magnetization value is probably due to noncollinear effects. In all samples the Curie temperature is very close to the blocking temperature, T_b , of the largest clusters in the

FIG. 1. Resistance vs temperature curves for the LaPb(\circ), LaPbFe(\square), NdPb(\diamond), and NdPbFe(\triangle) samples obtained under 0 (open symbol) and 6 T (full symbol) applied magnetic fields.

assembly.¹¹ At this temperature, bifurcation between ZFC and FC curves occurs losing the magnetization process its reversibility. The observed T_c values are clearly higher for the La phases than for the Nd ones. The introduction of iron in the samples causes an important decrease in the temperature of the ferromagnetic ordering (see Table II) following the same behavior observed for the semiconductor-metal transition.

The thermal evolution of the magnetization under 1 T applied field for all compounds is reported in Fig. 3(a). The observed behavior is essentially similar, but important differences on the magnetic moments are observed. The values of these moments are higher for the La phases than for the Nd ones, as was also observed for the T_c values. The influence on the magnetic moment values when introducing Fe is drastic, as was observed for $\text{La}_{0.7}\text{Ca}_{0.3}\text{Mn}_{1-x}\text{Fe}_x\text{O}_3$.¹² In this

TABLE II. Values of Curie temperatures, T_c , magnetization per magnetic ion, $M/N\mu_B$ at 10 K and 7 T, and transition temperature in the resistance behavior, T_{SC-M} , for the studied samples.

Sample	T_c (K)	$M/N\mu_B$	T_{SC-M} (K)

$\text{La}_{0.7}\text{Pb}_{0.3}\text{Mn}_{0.9}\text{Fe}_{0.1}\text{O}_3$	215(5)	2.79(10)	135(5)
$\text{Nd}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$	165(5)	3.30(10)	140(5)
$\text{Nd}_{0.7}\text{Pb}_{0.3}\text{Mn}_{0.9}\text{Fe}_{0.1}\text{O}_3$	75(5)	2.52(10)	115(5)

FIG. 2. Zero field cooling (ZFC, increasing temperature arrow) and field cooling (FC, decreasing temperature arrow) magnetization vs temperature curves for the studied samples, measured at $H_{app}=8$ kA/m.

way, decreases of a 49% for the NdPb and a 15% for the LaPb compositions have been measured at 10 K.

Values of the magnetization per magnetic ion at 10 K and up to 7 T applied field for all compositions are summarized in Table II. LaPb and LaPbFe compositions show the same features reaching quickly the magnetic saturation and keeping constant the difference in the magnetic moment found at 1 T applied field [see Fig. 3(b)]. The observed saturation moment for the LaPb phase agrees well with that expected for the volumetrically determined Mn^{3+}/Mn^{4+} composition. For the LaPbFe compound the magnetic moment is clearly lower than that calculated by adding Mn and Fe magnetic moments, but not so low as correspond to a fully antiparallel ordering of the Fe^{3+} ions. This fact suggests the presence of canted spins in the antiferromagnetic couplings induced by the iron ions.

For NdPb and NdPbFe the spins are not fully aligned under the applied maximum fields (7 T). The magnetic moment of the Fe phase is considerably lower. However, the slow evolution of the magnetization curve indicates that lower differences in the values of the magnetic moments should be probably measured at higher applied fields. These results together with the whole appearance of the ZFC curves suggest the presence of antiferromagnetic interactions Fe–O–Mn and that the Nd ions are not magnetically ordered even at 10 K.

Finally, it is to note that both the T_c and T_{SM-M} values are lower for the Nd phases than for the La ones. This fact is in good agreement with the lower ionic radii of the Nd^{3+} ions and the corresponding larger distortion of its perovskite-type structures. Besides, the introduction of Pb ions causes a similar effect that the Sr ones on the critical temperatures because of its similar ionic radii. These values correspond to

FIG. 3. (a) Magnetization vs temperature curves, $M(T)$, measured at $H_{app}=1$ T, and (b) hysteresis loops measured at 10 K for the studied samples.

the less distorted structures and give rise to the greater T_c and T_{SM-M} values observed in these type of compounds.⁸

The influence of 90 MeV ^{16}O ion irradiation on the electric and magnetic properties of epitaxial thin films of $\text{La}_{0.75}\text{Ca}_{0.25}\text{MnO}_3$ is studied. These films were deposited on $\text{LaAlO}_3(100)$ substrates by the pulsed excimer laser deposition technique. The thickness of each film was about 3000 Å. The high quality of the films was ensured by x-ray diffraction and transport measurements. The films were irradiated with 90 MeV oxygen ions at different doses (10^{11} – 10^{14} ions/cm²). It is observed that at a low dose of 10^{11} ions/cm² the resistivity peak temperature (T_p) and the Curie temperature (T_c) increase, however as the dose is increased further, the T_p and T_c decrease. At the higher dose of 10^{14} ions/cm², the film becomes insulating and does not show any peak in the resistivity–temperature curve down to 60 K. These results are discussed in terms of the effects of ion induced compositional inhomogeneity and strain on the film properties. © 1998 American Institute of Physics. [S0021-8979(98)45011-4]

INTRODUCTION

Interest in the transport properties of doped perovskite oxides of the type $\text{A}_{1-x}\text{B}_x\text{MnO}_{3+y}$ ($\text{A}=\text{La}, \text{Nd}, \text{Y}; \text{B}=\text{Ca}, \text{Ba}, \text{Sr}$) has grown rather sharply during the past few years since the discovery of colossal magnetoresistance (CMR) behavior in these compounds.^{1–4} A prominent feature of these materials is the occurrence of a peak in resistivity (T_p) close to the ferromagnetic transition temperature (T_c) and a spectacular (up to a thousandfold) reduction in the resistivity upon application of a magnetic field of several tesla.^{4,5} Earlier studies have shown that the transport in these oxides is strongly influenced by the $\text{Mn}^{+3}/\text{Mn}^{+4}$ ratio (i.e., the amount of doping).^{6,7} It has also been established that the transport and magnetization in these oxides is primarily controlled by the $\text{Mn}^{+3}\text{--O--Mn}^{+4}$ network. The transport is considered to occur by the so called Zener double exchange model,⁸ although the validity of this model has increasingly been questioned in recent years.⁹ As the oxygen content in these materials decreases, the resistivity increases and the magnetic transition temperature shifts to lower temperature.¹⁰ The presence of grain boundaries modifies the magneto-transport behavior completely.¹¹ External pressure has also been shown to influence the semiconductor (paramagnetic)–metal (ferromagnetic) transition.¹² Thus, it appears that the magneto-transport properties of doped manganese oxides are very sensitive to lattice strain and disorder. The strain can influence the $\text{Mn}^{+3}\text{--O--Mn}^{+4}$ bond angle as well as bond distances while other forms of disorder could additionally influence the charge imbalance.

It is well known that irradiation of solids with energetic particles leads to creation of a wide variety of defect states

therein.¹³ In particular, damage by energetic ion beams has been well studied over the past decades. At medium ion energies (keV range), the damage is caused by the nuclear loss, whereas at higher energies (MeV–GeV range) it is caused by the electronic loss mechanism. Since irradiation can lead to a controlled introduction of defect states in the material system, it has been and is being beneficially used to control the material properties. Since the magnetic properties are also affected significantly by defects, irradiation can be used to control such properties as the coercivity and the retentivity of the materials, which are important in different applications.

In this work, we have examined the effects of 90 MeV ^{16}O irradiation on the structural, magnetic, and transport properties of $\text{La}_{0.75}\text{Ca}_{0.25}\text{MnO}_3$ (LCMO) thin films. The results are presented in terms of the observed shift in the ferromagnetic transition temperature, changes in the resistivity behavior and the activation energy, structural modifications, and change in the magnetization of the films, as a function of the irradiation dose.

EXPERIMENT

The LCMO target used for the deposition of the thin films was prepared by solid state reaction starting from the respective elemental oxides following a standard ceramic route. The LCMO thin films, having thicknesses of about 3000 Å, were grown on $\text{LaAlO}_3(100)$ single-crystal substrates by the pulsed laser deposition technique. A KrF excimer laser ($\lambda = 248$ nm, $t_p = 20$ ns) was employed and ablation was performed at a laser energy density of 2 J/cm². The substrate temperature was maintained at 700 °C while the oxygen partial pressure was 200 mTorr during deposition. The deposited films were cooled to room temperature in 500 Torr oxygen ambient. The irradiations of epitaxial thin films of LCMO were performed on the pelletron accelerator with 90 MeV oxygen ions at different doses, e.g., 10^{11} , 10^{12} , 10^{13} ,

FIG. 1. X-ray diffraction patterns for the as-deposited film and for the films irradiated at different doses of 1×10^{11} , 1×10^{12} , 1×10^{13} , and 1×10^{14} ions/cm².

and 10^{14} ions/cm². The irradiated samples were characterized for structural quality by x-ray diffraction. The resistivity of each sample was measured using a standard four probe technique. The magnetization curves as a function of temperature from 300 to 80 K were obtained using a vibrating sample magnetometer (VSM).

RESULTS AND DISCUSSIONS

The electronic and nuclear energy loss values for 90 MeV ^{16}O ions in LCMO, calculated using the TRIM code simulation program are 2.5 MeV cm²/mg and 1.44 keV cm²/mg, respectively. Also, the range of ions used in our experiments is about 39 μm , indicating that the entire passage of ions in the film is dominated by the electronic energy loss. It is well known that in this regime of energy loss continuous columns of amorphous/defected material are created after irradiation if the loss is more than a threshold value.¹⁴ Using Szenes's model¹⁴ one can calculate the threshold value of electronic energy loss for the formation of columnar defects. For LCMO, this value comes out to be about 20 MeV cm²/mg, which is much larger than the energy loss in our experiments. Therefore, the possibility of formation of columnar defects is ruled out and it is quite likely that small chaplets¹⁵ of defected regions are formed in the LCMO lattice in our experiments. Indeed, our x-ray diffraction (XRD) data showed that amorphization does not occur in the system, however, stoichiometry defects are introduced with increasing ion dose. We highlight this aspect by focusing on the (004) XRD peak for LCMO (Fig. 1). In the sample irradiated at the low dose of 10^{11} ions/cm² however, no discernable change in the line shape is seen. The peak is, however, seen to shift slightly towards higher theta value, indicating a decrease in the d value, which implies modification of strain.

FIG. 2. Resistivity vs temperature curves for the as-deposited film and films irradiated at different ion doses.

It can be seen that for dose values of 10^{12} and 10^{13} ions/cm² shoulders appear on the XRD peak and they grow with the dose. At a dose of 10^{14} ions/cm² phase disproportion is apparent.

Figure 2 shows the resistivity (ρ) as a function of temperature for the as-deposited and irradiated films. At a dose of 10^{14} ions/cm² the film does not show any transition from the insulating state to the metallic state, at least down to 60 K. The plot of T_p versus irradiation dose is shown in Fig. 3. Initially at a lower dose of 10^{11} ions/cm², the T_p increases and then starts decreasing for a dose of 10^{12} ions/cm² and above. Figure 3 also shows the variation of activation en-

FIG. 3. Dependence of the resistivity peak temperature (T_p) and the activation energy (E_a) as a function of irradiation dose.

FIG. 4. Magnetization vs temperature curves for the as-deposited film and the film irradiated at a dose of 1×10^{11} ions/cm². The arrows show T_c 's. The inset shows the data for the film irradiated at a dose of 1×10^{14} ions/cm².

ergy, E_a , for hopping transport in the semiconducting region ($T > T_p$) with the irradiation dose. These values were obtained from $\ln(\rho)$ vs $1/T$ plots. The lower value of activation energy for the dose of 10^{11} ions/cm² again suggests release of deposition induced microscopic strains. The increase in the activation energy with irradiation dose can be attributed to the strain developed in the LCMO lattice due to irradiation induced stoichiometry defects revealed by the XRD data.

The magnetization curves as a function of temperature for the as-deposited film and the film irradiated at the lowest dose of 1×10^{11} ions/cm² are compared in Fig. 4. The arrows show the Curie temperature (T_c). It clearly shows that T_c for the film irradiated at 1×10^{11} ions/cm² is more than that of the unirradiated film, establishing a T_c - T_p correlation. At higher doses this transition temperature decreases below that of the unirradiated film. This behavior of T_c with the irradiation dose is also consistent with that of T_p . It can be seen from the inset of Fig. 4 that the magnetization curve for the film irradiated at 1×10^{14} ions/cm² shows no well defined transition from the paramagnetic to the ferromagnetic state as we decrease the temperature. This can be explained if one visualizes the formation of small chaplets of amorphous and/or inhomogeneities uniformly distributed throughout the film. Evidence for this is obtained from the XRD data dis-

cussed earlier. Such type of defects is capable of affecting the angle and length of the $\text{Mn}^{+3}\text{-O-Mn}^{+4}$ bond, which in turn affects the double-exchange interaction.

In conclusion we have explained the effects of 90 MeV ^{16}O ion irradiation on the epitaxial $\text{La}_{0.75}\text{Ca}_{0.25}\text{MnO}_3$ thin films grown by pulsed laser deposition. The electrical and magnetic measurements show that the resistivity peak temperature (T_p) and ferromagnetic transition temperature, i.e., Curie temperature (T_c), shift towards lower value with irradiation dose, except for the case of a low dose of 1×10^{11} ions/cm². The lower dose apparently relaxes the LCMO lattice, releasing deposition induced microscopic strain present in the as-deposited films, causing an increase in T_p and T_c and a decrease in the activation energy. At high doses, irradiation induced disorder introduces compositional inhomogeneity and related strain in the films which apparently affect the angle and length of the $\text{Mn}^{+3}\text{-O-Mn}^{+4}$ bond, and hence the exchange interaction between the cations.

$\text{La}_{1-x}\text{Li}_x\text{MnO}_3$ ($x=0, 0.1, 0.2$, and 0.3) were synthesized by using conventional solid state reaction and partial melting technique. The compounds were determined to be of rhombohedral structure by x-ray powder diffraction. For the $x=0.2$ and $x=0.3$ samples, room temperature neutron powder diffraction patterns were collected and analyzed with the Rietveld method. The analysis showed that the Li substitutes onto the La site in the rhombohedral perovskite lattice. Resistivities were measured between 4.2 K and room temperature in the magnetic fields of 0, 1, 2, 4, 8, and 13 T. A wide semiconductor-metal transition at temperatures between 160 and 210 K or between 200–230 K were observed for both samples with $x=0.2$ and 0.3 , respectively. Large magnetoresistances above 20%–80% were achieved at fields from null to 13 T over a wide temperature range from the ferromagnetic transitions down to 4.2 K. However, the $x=0$ and 0.1 samples show a semiconducting behavior in resistivity measured between 77 and 300 K. © 1998 American Institute of Physics. [S0021-8979(98)45111-9]

I. INTRODUCTION

Recent discovery of colossal magnetoresistance (CMR) phenomenon in doped LaMnO_3 perovskite (LMO)^{1–4} which exhibit a field-induced change in electrical conductivity by many orders of magnitude, has stimulated much research worldwide because of its importance both for fundamental research in solid state physics and for practical application in magnetoelectronics. Upon doping La^{3+} by divalent ions, both Mn^{3+} and Mn^{4+} ions are present. Electron hopping occurs via the double-exchange (DE) mechanism.^{5–7} Up to now, substitution of La^{3+} by divalent ions such as Ca, Sr, Ba, Pb, or Cd have been widely studied in order to achieve mixture valences of Mn^{3+} and Mn^{4+} . It was found that the geometry of the Mn–O–Mn bond plays a crucial role since the oxygen ion mediates the DE. Distortion of the crystal structure leads to the buckling of octahedral network,⁸ and changes the interatomic distance and bond angle, hence influencing the electron hopping and DE interaction. The value of MR above 10^5 was achieved in doped LMO thin films with optimized straining of the lattice.⁹ This reflects that the lattice distortion favors the CMR. The DE will be enhanced if the Mn–O distance decreased. To decrease Mn–O distance, studies have been done on substitution of La^{3+} by smaller $3+$ ions, (eg, Pr, Y, Nd) or substitution Ca by Y.^{10,11}

With decreasing average ionic radius of the La site, MR increases dramatically.¹⁰ Films of $\text{La}_{0.6}\text{Y}_{0.07}\text{Ca}_{0.33}\text{MnO}_3$ on LaAlO_3 substrate give a much higher MR value (10^9) than the undoped La–Ca–Mn–O films.⁹ From a practical viewpoint, large MR over a wide temperature range is highly desirable. However, MR was widely observed to be restricted to a narrow temperature range around ferromagnetic transition (FT) in single crystals and epitaxial thin films of doped LMO. Although polycrystalline thin films showed MR at a relative wide temperature range, the resistivity is much higher than that of epitaxial thin films.^{12–14} The large resistivity would give high levels of electrical noise. For the occurrence of DE, the amount of Mn^{4+} should be sufficient enough in the LMO and $x=0.3$ was found to be optimum doping level in $\text{La}_{1-x}\text{M}_x\text{MnO}_3$ ($\text{M}=\text{Ca}, \text{Sr}, \text{Ba}, \dots$) which corresponds to 30% Mn^{4+} . Compared with substitution of La by the $2+$ ions, substitution by $1+$ ions, such as H^+ , Li^+ , Na^+ , K^+ , or Rb^+ , will be easy to achieve a high percentage of Mn^{4+} with the same doping level as that by $2+$ ions substitution. For every ion with $1+$ valence substitution for trivalent lanthanum ion, two Mn^{3+} need to be oxidized to Mn^{4+} . H^+ radius is so small that it is expected to distribute in atomic gaps instead of occupying La sites. While Na and K are not stable, they evaporate significantly at high temperatures.¹⁵ In this article, we report our studies on LMO with Li^+ partially substituted for La instead of using a divalent ion for doping into La site. The optimum Li-doped LMO

FIG. 1. XRD patterns of powdered $\text{La}_{1-x}\text{Li}_x\text{MnO}_3$ (a) and (b) and surface of samples prepared by partial melting (c).

shows a ferromagnetic transition at 230 K which is the same as that in Ca-doped LMO and a nearly constant magnetoresistance $\Delta\rho/\rho_0=20\%-80\%$ with the application of magnetic fields from 1 up to 13 T over a very wide temperature range between 230 and 4.2 K.

II. EXPERIMENT

The Li-doped LMO samples were synthesized by conventional solid state reaction and partial melting technique. High purity powders of La_2O_3 , LiCO_3 , and MnCO_3 were weighed according to nominal composition of $\text{La}_{1-x}\text{Li}_x\text{MnO}_3$ ($x=0, 0.1, 0.2$, and 0.3). After mixing them well, these powders were pressed into pellets 10 mm in diameter. The pellets were first sintered at a temperature of 1100 °C for 24 h (referred to as sintered samples). After grinding and pressing, the pellets were then partially melted at a temperature of 1500 °C for 10 min and rapidly cooled down to 900 °C and quenched in air (referred to as partially melted samples). A post annealing in O_2 at 700 °C was carried out for some samples. Bar samples were cut from the as-prepared bulks for a standard four-probe resistance-temperature (R-T) measurement. The resistivity of the samples were measured as a function of temperature between 300–77 K at null field and 4.2–300 K at fields from null up to 13 T. X-ray diffraction (XRD) neutron powder diffraction, and scanning electron microscopy (SEM) were carried out for characterization of the samples.

III. RESULTS AND DISCUSSIONS

The compounds were determined to be of rhombohedral structure by x-ray powder diffraction as shown in Fig. 1 and contain a small amount of unknown impurity phase for as-sintering samples [Figs. 1(a) and 1(b)]. The amount of impurity phase was found to gradually increase with an increasing Li doping level. Room-temperature neutron powder diffraction patterns of the $x=0.2$ and $x=0.3$ as-sintered samples were analyzed with the Rietveld method. The patterns were fitted with space group $R3c$ and Bragg R factor of 2.3% and 5.0%, respectively. A neutron powder diffraction pattern of the $x=0.2$ sample is shown in Fig. 2 with the fit to

FIG. 2. Room-temperature neutron powder diffraction pattern for as-sintered sample ($x=0.2$) and Rietveld refinement of pattern.

the data. Most of the peaks are well fitted by a rhombohedral perovskite structure. The analysis showed Mn and O are fully occupied and concentrations of La are 0.884 and 0.832 for samples with $x=0.2$ and 0.3 , respectively, indicating that the Li substitutes onto the La site in the rhombohedral perovskite lattice. However, the exact doping level of Li is much lower than that in nominal compositions. The as-sintered samples reveal very porous morphologies by scanning electron microscopy and have a high resistance at room temperature due to a large amount of grain boundaries. As-partially melted samples are of high density with lower resistance at room temperature and contains less impurities than as-sintered samples as shown in Fig. 1(c). The intensity ratios of (104)/(110), (006)/(202), and (018)/(030) reflections of the partially melted samples are higher than those of the as-sintered samples with the same Li doping level. This reveals that the partially melted samples have a (001) orientation tendency when compared with as-sintered one. The temperature dependencies of resistivity at a temperature range between 77 and 300 K is shown in Fig. 3 for both $x=0.2$ and 0.3 as-partially melted samples annealed in O_2 . These two samples exhibit a semiconductive-metallic transition between 200–230 K and 160–210 K, respectively. However, samples with $x=0$ and 0.1 are semiconductive without

FIG. 3. Resistivity-temperature of Li-doped LMO samples partially melted and annealed in O_2 between 77 and 300 K at null field.

FIG. 4. Resistivity-temperature of as-partially melted sample with $x=0.2$ between 4.2 and 300 K in different fields.

any transition above 77 K. Figure 4 shows a temperature dependence of the resistance for an as-partially melted sample ($x=0.2$) at field of 0, 1, 2, 4, 8, and 13 T. At zero field, the resistance increases with decreasing temperature until 230 K at which a ferromagnetic transition (FT) takes place. Below 230 K, the resistance remains constant between 230 and 170 K which is wider than that annealed in O_2 (Fig. 3) and reduces slowly with further cooling down to 77 K and then increasing with a further decrease of temperature. With increasing magnetic fields, the FT was gradually increased up to 270 K. Meanwhile, the room-temperature resistance decreases, indicative of a typical ferromagnetic transition behavior and paramagnetism above FT. Magnetoresistance, $\Delta\rho/\rho_0 = [\rho_0 - \rho_H]/\rho_0$, shows a nearly constant values of 17%–20%, 22%–30%, 30%–48%, 45%–65%, and 52%–80% for fields of 1, 2, 4, 8, and 13 T, respectively, over a very wide temperature range between 4.2 and 230 K as shown in Fig. 5. Such a large MR over a wide temperature range achieved in the Li-doped $LaMnO_3$ is the same as that

FIG. 5. Magnetoresistance of an as-partially melted sample with $x=0.2$ between 4.2 and 300 K in different fields.

observed in polycrystalline thin films of Ca-doped $LaMnO_3$ with a field of 5 T¹⁴ and wider than Na^{1+} doped LMO bulks and thin films.¹²

The magnetic moment versus temperature ($m-T$) for an as-partially melted sample with $x=0.2$ measured at 50 Oe shows a typical ferromagnetic transition at 230 K which is in accord with the onset of transition in the resistance-temperature curve (Fig. 4). However, the ferromagnetic transition width derived from $m-T$ is narrow (215–230 K) which could not account for the constant value of resistance in a wide temperature range between 230 and 170 K. The SEM morphologies of the Li and Ca doped $LaMnO_3$ show that the partially melted samples are very dense and no clear grain boundaries can be seen. Grain sizes are much larger than that of polycrystalline bulk samples synthesized by a conventional solid state reaction (as-sintered samples). Since both Li and Ca doped LMO samples prepared by the partial melting technique are polycrystalline and without any preferred orientation as seen from their XRD, the possible effect of grain boundaries on the MR over a wide temperature range seems unclear for the Li-doped $LaMnO_3$.^{11,16} In addition, the radius of the Li^{1+} is much smaller (0.78 Å) than La^{3+} . Distortion of the lattice due to the Li substitution for La will be larger than that of Ca, Sr, and other 2+ ions and Na^{1+} doped $LaMnO_3$ and induce large amount of crystal defects, nonuniform substitutions, and oxygen deficiencies which may lead to the broadening in the resistance-temperature curve and hence cause the large MR over a broad temperature range. The real origin of the broadening of resistance in the R-T curve is unclear and needs further study. From a practical viewpoint, the large MR over such a wide temperature range is beneficial for the application of magnetoelectronic devices fabricated by the CMR magnanites. To achieve a larger and constant MR near room temperature, fabrication of thin films of the Li doped $LaMnO_3$ and optimization of oxygen are necessary.

Antiferromagnetic resonance (AFMR), dynamic conductivity, and dielectric permittivity have been studied in the $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ perovskites at a frequency range of $\nu = 3\text{--}33\text{ cm}^{-1}$ by the use of a quasi-optical backward-wave-oscillator technique. Two AFMR modes have been observed in LaMnO_3 and $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$. Temperature dependencies of their resonance frequencies, linewidths, and mode contributions to a static magnetic permeability have been obtained and corresponding parameters of magnetic interactions have been extracted. A jump in the dielectric permittivity $\epsilon'(T)$ was found at $T = 100\text{--}120\text{ K}$ in $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$, which indicates the existence of an additional phase transition (probably, a polaron ordering) besides the ferromagnetic transition at 170 K. A sharp increase of the dynamic conductivity $\sigma'(\nu, T)$ was observed near Curie temperature (285 K) at a metal–semiconductor transition in $\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$, which was slightly smaller than its static value. © 1998 American Institute of Physics. [S0021-8979(98)31811-3]

The recent observation of the colossal negative magnetoresistance in doped perovskites $\text{R}_{1-x}\text{A}_x\text{MnO}_3$, where R is a trivalent rare-earth ion and A is a divalent ion such as Ca or Sr,¹ has attracted considerable interest in these compounds. Their magnetic, electronic transport, structural, and optical properties exhibit a remarkable variation with the doping level.^{2–4}

The parent compound LaMnO_3 (Mott-type insulator) has a canted antiferromagnetic layer (A_yF_z) structure with a Neel temperature $T_N \approx 140\text{ K}$.^{5–7} Manganese ions Mn^{3+} have a $3d^4$ electronic configuration with a total spin $S = 2$, where three electrons occupying t_{2g} orbitals may be considered as a local spin of $S = 3/2$, while the remaining electron occupies an e_g orbital hybridized with oxygen $2p$ states. The spins of the t_{2g} and e_g electrons are parallel aligned due to on-site Hund coupling. The substitution of the rare-earth ions by Sr (or Ca) ions results in doping of holes to the e_g orbitals and a transition from a canted antiferromagnetic insulating state to a ferromagnetic metallic state,^{1,2,8} which is stabilized due to a double exchange.⁹

Recent spectroscopic investigations of the doped lanthanum manganites indicate that their dynamic properties change drastically through the phase transitions and are very sensitive to the doping level. An infrared study of the optical conductivity of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ has shown a large variation of the electronic structure in a wide frequency range ($\sim 2\text{ eV}$) with the spin polarization of the conduction carriers⁴ and a shift of phonon frequencies at the ferromagnetic metal–insulator transition.¹⁰ Inelastic neutron scattering experiments have revealed spin excitations in pure LaMnO_3 ,^{7,11} and these dramatically change with doping level.¹² In this work we performed investigations of antifer-

romagnetic resonance (AFMR), dynamic conductivity, and dielectric permittivity of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ manganites in the submillimeter frequency range by means of a quasi-optical backward-wave-oscillator technique.^{13,14}

Single crystals of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0, 0.05, 0.1, 0.15$, and 0.175) were grown by the floating zone method with radiation heating in an air atmosphere. X-ray powder diffraction measurements showed that grown materials were of single phase. However, x-ray topography has revealed a twin structure in the crystals.

Resistance, $\rho(T)$, was measured using the four-probe method at $T = 4.2\text{--}400\text{ K}$ in magnetic fields H up to 12 kOe. Magnetization $M(T, H)$ and ac magnetic susceptibility $\chi_{ac}(T)$ measurements were performed in magnetic fields $H \leq 12\text{ kOe}$ at $T = 4.2\text{--}400\text{ K}$.

The transmission $T(\nu)$ and phase shift $\Delta\varphi(\nu)$ spectra of thin plane-parallel plates were measured using a quasi-optical submillimeter backward-wave-oscillator spectrometer^{13,14} in the frequency range $\nu = 3\text{--}33\text{ cm}^{-1}$ at temperatures of $5\text{--}300\text{ K}$. The complex dielectric permittivity $\epsilon(\nu, T) = \epsilon' + i\epsilon''$ as well as the dynamic conductivity $\sigma(\nu, T)$ were determined from the $T(\nu)$ and $\Delta\varphi(\nu)$ spectra using Fresnel's formulas for the transmission and phase shift of the plane-parallel plate.¹⁵ In order to take into account the AFMR mode contribution we used a harmonic oscillator model for a permeability dispersion:

$$\mu = 1 + \sum_i \Delta\mu_i \nu_i^2 / (\nu_i^2 - \nu^2 + j\nu\Delta\nu_i), \quad (1)$$

where ν_i , $\Delta\nu_i$, and $\Delta\mu_i$ are the resonance frequency, linewidth, and mode contribution to the static permeability of the i th mode, respectively, $j = \sqrt{-1}$.

LaMnO_3 : In the transmission spectra of the pure LaMnO_3 we observed two lines close together, which appeared at $T < T_N = 140\text{ K}$. We have identified the lines with

^{a)}Electronic mail: mukhin@ss.gpi.ru

FIG. 1. Temperature dependence of the AFMR frequencies in $\text{LaMn}_{1-x}\text{Sr}_x\text{O}_3$ for $x=0$ and 0.05. Arrows indicate the corresponding Neel temperatures.

two AFMR modes and have fitted $T(\nu)$ spectra using Fresnel's formulas and Eq. (1) for the permeability. The temperature dependence of the AFMR frequencies is shown in Fig. 1. The values of the linewidth, mode contribution, and complex dielectric permittivity are equal to $\Delta\nu_{1,2} \approx 0.5 \text{ cm}^{-1}$, $\Delta\mu_{1,2} \approx 0.035$, and $\epsilon' \approx 20.5$, $\epsilon'' \approx 0.1$, respectively, at $T=80 \text{ K}$. An inelastic neutron scattering study of LaMnO_3 gives the gap for the spin waves at about 19.8 cm^{-1} at 20 K (Ref. 7) and 19.4 cm^{-1} at 8 K ,¹¹ in agreement with our resonance frequency values of 18.1 and 17.3 cm^{-1} at 4.2 K (Fig. 1).

According to Refs. 6 and 7 the antiferromagnetic spin axis in LaMnO_3 is along the b axis of the orthorhombic Pbm crystal and a small spin canting takes place along the c axis (magnetic structure of the A_yF_z type). There are two AFMR modes in the crystal whose frequencies are determined by¹⁴

$$\nu_1 = \gamma(2H_E H_A^{cb})^{1/2}, \quad \nu_2 = \gamma(2H_E H_A^{ab} + H_D^2)^{1/2}, \quad (2)$$

where $H_A^{cb} = K_{cb}/M_0$, $H_A^{ab} = K_{ab}/M_0$, and $K_{cb,ab}$ are anisotropy constants for the cb and ab crystallographic planes, respectively, H_E and H_D are isotropic and antisymmetric exchange fields, respectively, $M_0/2$ is a sublattice magnetization, and γ is a gyromagnetic ratio. The first (quasiferromagnetic) mode is excited by $h||a$ and b axes, while the second (quasiantiferromagnetic) mode is excited by $h||c$ axis. The corresponding mode contributions are: $\Delta\mu_1^a = 4\pi\rho\chi_\perp$, $\Delta\mu_1^b = 4\pi\rho\chi_{\text{rot}}$ for mode 1 and $\Delta\mu_2^c = 4\pi\rho\chi_\perp$ for mode 2, where $\chi_\perp = M_0/2H_E$ and $\chi_{\text{rot}} = m_0^2/K_{cb}$ are transverse and rotation susceptibilities, respectively, $m_0 = \chi_\perp H_D$ is the weak ferromagnetic moment and $\rho \approx 6.5 \text{ g/cm}^3$ is the crystal density. Due to the twin structure of the investigated LaMnO_3 crystals both modes were observed simultaneously with nearly equal mode contributions at various polarization of radiation. Assuming equal volume for all six kinds of the twins and their even distribution in the sample we obtain $\Delta\mu_1 = 1/3(\Delta\mu_1^a + \Delta\mu_1^b)$ and $\Delta\mu_2 = 1/3\Delta\mu_2^c$ and then we may estimate $\chi_\perp \approx (1.4 \pm 0.2) \times 10^{-4} \text{ cm}^3/\text{g}$ and the corresponding exchange field $H_E \approx 3.3 \times 10^5 \text{ Oe}$. This value of the χ_\perp is in a reasonable agreement with the $\chi_\perp = (1.8 \pm 0.3)$

FIG. 2. Temperature dependence of the dielectric permittivity $\epsilon'_{1,2}(7.5 \text{ cm}^{-1})$ (a), dynamic $[\sigma'_{1,2}(7.5 \text{ cm}^{-1})]$ and static (σ_{dc}) conductivity (b) and ac magnetic susceptibility χ_{ac} (c) of $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$. Indices 1,2 correspond to the two crystallographic directions: 1— $[-110]$ and 2— $[-11-2]$.

$\times 10^{-4} \text{ cm}^3/\text{g}$ deduced from our static measurements. Using the interplane exchange constant obtained from an inelastic neutron scattering study of the spin waves in LaMnO_3 ,^{7,11} we can determine $H_E \approx 4 \times 10^5 \text{ Oe}$ that is close to our data. Using the value of the weak ferromagnetic moment for a single domain $m_0(T=78 \text{ K}) = 4.2 \pm 0.5 \text{ emu/g}$ deduced from our static measurements and anisotropy constant $K_{cb}(T=78 \text{ K}) \approx 3 \times 10^6 \text{ erg/g}$ ($\approx 6 \text{ cm}^{-1}/\text{ion}$) determined from the AFMR frequency we may estimate $\chi_{\text{rot}} = 6 \times 10^{-6} \text{ cm}^3/\text{g}$. The small value of the χ_{rot} , i.e., $\chi_{\text{rot}} \ll \chi_\perp$, explains the nearly equal mode contributions ($\Delta\mu_1 \approx \Delta\mu_2$) observed in our experiment. We note also the small contribution of the antisymmetric exchange field H_D into the AFMR frequency and nearly equal values of the anisotropy constants in different crystallographic planes that permit the use of a simple model of an uniaxial antiferromagnet to describe the spin waves in LaMnO_3 .^{7,11}

$\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$: Two AFMR modes were revealed for this composition, which in contrast to the pure LaMnO_3 , had significantly different frequencies (Fig. 1). What's more, the

FIG. 3. Temperature dependence of the dynamic $\sigma'_{1,2}$ (at $7-20 \text{ cm}^{-1}$) and static (σ_{dc}) conductivity and ac magnetic susceptibility (χ_{ac}) of $\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$.

samples (*b*-cut plane parallel plates) practically did not contain twins and we were able to determine excitation conditions and identify the modes: the low frequency mode (ν_1) observed at the $h\parallel a$ axis was identified as a quasiferromagnetic mode, while the high frequency mode (ν_2) excited by the $h\parallel c$ axis was identified as a quasiantiferromagnetic one. The values of the mode contributions and linewidths are ($T = 10 \text{ K}$): $\Delta\mu_1 = 0.016 \pm 0.003$, $\Delta\mu_2 = 0.015 \pm 0.003$, $\Delta\nu_{1,2} \approx 2 \text{ cm}^{-1}$.

We assumed above that the magnetic structure is of the A_2F_z type. This conclusion is confirmed by the neutron scattering and magnetic study of the $\text{La}_{0.96}\text{Sr}_{0.04}\text{MnO}_3$,¹⁶ where the magnetic structure remains similar to that of pure LaMnO_3 , however, with increased value of a canting angle. According to our static measurements of $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ the magnetic susceptibilities $\chi_a \approx \chi_c = (1.3-1.9) \times 10^{-4} \text{ cm}^3/\text{g}$, $\chi_b = (5.3 \pm 0.5) \times 10^{-4}$, and spontaneous moment along the *c* axis $m_0 = 18 \pm 4 \text{ emu/g}$ are in agreement with the A_2F_z magnetic structure. However, we note a noticeable increase (about four times) of the canting angle and significant decrease of the anisotropy constant in the *cb* plane. The estimated values of the K_{cb} are: $(0.7 \pm 0.2) \times 10^6 \text{ cm}^3/\text{g}$ from the AFMR data and $(0.6 \pm 0.2) \times 10^6 \text{ cm}^3/\text{g}$ from the rotation susceptibility (χ_b).

The dielectric properties of $\text{La}_{0.95}\text{Sr}_{0.05}\text{MnO}_3$ are similar to LaMnO_3 , however we note their anisotropy and higher dielectric losses, in particular, $\epsilon'_a \approx 24$, $\epsilon''_a = 0.6-0.7$, and $\epsilon'_c \approx 20$, $\epsilon''_c \approx 0.2-0.3$ for $\nu = 5-13 \text{ cm}^{-1}$ and $T = 80 \text{ K}$.

$\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$: Magnetic, dielectric, and transport properties of this composition suffer significant changes as compared with previous ones. We did not observe magnetic modes in the range $5-20 \text{ cm}^{-1}$ since the magnetic ordering at $T < T_C \approx 170 \text{ K}$ is of the ferromagnetic type and a ferromagnetic resonance is expected at much lower frequencies. However, apparent anomalies were observed in the temperature dependence of the dielectric permittivity and conductivity (Fig. 2). A pronounced jumplike behavior for $\epsilon'(T)$ and a maximum for $\sigma'(T)$ between 100 and 120 K indicate the existence of an additional phase transition besides the magnetic transition at T_C . The anomalous behavior of the ac magnetic susceptibility at $T < T_C$ [Fig. 2(c)] confirms this

conclusion. One possible origin of this transition may be related to a polaron ordering connected with a freezing of holes on the lattice sites.¹⁷

We note also an anisotropy of the ϵ' and σ' for different crystallographic directions [Figs. 2(a) and 2(b)]. The dynamic conductivity $\sigma'(T)$ is considerably greater than the static one, $\sigma_{dc}(T)$ [Fig. 2(b)]. This indicates that not only free charge carriers contribute to the dynamic σ' but also contributions from the localized carriers and crystal lattice are of importance at the submillimeter wavelengths.

$\text{La}_{0.825}\text{Sr}_{0.175}\text{MnO}_3$: For the high conducting composition ($x = 0.175$) a considerable decrease of the transmission $T(\nu)$ for the 0.026 mm plate on lowering the temperature was observed near the ferromagnetic phase transition at $T_C \approx 285 \text{ K}$, accompanied by a metal-semiconductor transition. In particular, T decreases from 2×10^{-3} at 300 K to 10^{-4} at 280 K . The extracted dynamic conductivity $\sigma'(\nu, T)$ is slightly smaller than its static value $\sigma_{dc}(T)$ and exhibits a sharp increase at the phase transition (Fig. 3). The main contribution to $\sigma'(\nu, T)$ is Drude-like, practically without frequency dispersion. The real part of the dielectric permittivity amounts to $\epsilon'(T = 295 \text{ K}) = 37$ and shows no frequency dispersion.

In conclusion, this study of the submillimeter properties of the $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ perovskites shows the intimate relations between their magnetic excitations, charge carriers, and crystal lattice dynamics and gives insight into the origin of their unusual magnetic, electronic, and structural properties.

Unusual substitutional properties of Ru in the $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ system

S. Sundar Manoharan,^{a)} H. L. Ju, and Kannan M. Krishnan^{b)}

Lawrence Berkeley National Laboratory, Materials Sciences Division, 72-150, Berkeley, California 94720

$\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$, $0 \leq x \leq 0.2$ samples were prepared both in bulk and thin film formed using pulsed laser deposition. Magnetization measurements of bulk samples indicate a marginal decrease in T_c from 366 to 335 K up to 15% Ru substitution in Mn site. X-ray diffraction of the $\langle 100 \rangle$ oriented epitaxial films indicate a monotonic increase in the lattice parameter with Ru doping. The magnetoresistive behavior of the Ru substituted films are comparable with the parent $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films. Unlike other elemental substitution in Mn sites, the effect of Ru to stabilize magnetic ordering at elevated temperatures is exceptional. © 1998 American Institute of Physics. [S0021-8979(98)26911-8]

Hole-doped manganese oxides exhibit a very large negative magnetoresistance at temperatures close to their paramagnetic to ferromagnetic transition.¹⁻³ The magnetic interaction is mediated by the double exchange interaction between the Mn^{3+} and Mn^{4+} ions. It is now understood that at least three factors govern the insulator to metal (I-M) transition in these materials:^{4,5} the average size of the cations (A, Ln, in $\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$) where A is a divalent dopant and Ln is a lanthanide element, the mixed valence state of manganese (hole carrier density) and the size mismatch between the A and Ln cations. However, preliminary studies of the substitution of metallic elements for manganese in such perovskite manganites has shown that it is possible to dramatically modify their magnetic and transport properties. For example,⁶ $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ can be driven from insulator to a metal by doping with Cr and Co in Mn sites. In all these attempts it has been observed that any substitution which alters the Zener pairs ($\text{Mn}^{3+}/\text{Mn}^{4+}$) drastically reduces the Curie temperature. The prospects for realizing practical application of these materials largely depends on their low field response and achieving a Curie temperature, T_c above room temperature. Of all the materials reported so far, Ba, Sr, and Pb^{7} substituted $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ shows T_c above 300 K. On the other hand, all substitutions including those on Mn sites drastically reduce T_c . Despite this background, we attempted to evaluate the effect of Ru substitution for three reasons: (i) 4d orbitals of Ru are more delocalized compared to the 3d transition metals; (ii) SrRuO_3 is a well known ferromagnet and a highly conducting perovskite oxide by virtue of Ru:4d-O:2p exchange interactions, and (iii) it is now fairly well understood that the conductivity in manganites is proportional to the ferromagnetic ordering and therefore we could expect better exchange interactions between Mn and Ru in a mixed perovskite. In this article, we present the synthesis of both bulk and thin films of $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ (where $0.0 \leq x \leq 0.2$). We document

for the first time that Ru doping upto 15 at. % in Mn site does not lower the ferromagnetic ordering as observed for other transition metals.

The Ru doped manganites, $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ were prepared in the form of pellets by calcining mixtures of oxides of La_2O_3 , SrCO_3 , MnCO_3 , and RuO_2 initially at 1100 °C and at 1400 °C after intermittent grinding. Thin films were grown on LaAlO_3 substrates at 300 mTorr oxygen partial pressure and at a substrate temperature of 680 °C by pulsed laser deposition (PLD). The KrF excimer laser employed for the deposition was operated with a pulse energy density of 2 J/cm² and 5 Hz pulse rate. After deposition the films were cooled to room temperature in 200 Torr of O_2 pressure. The bulk polycrystalline samples of the parent $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ and the Ru substituted compounds are both single phase with orthorhombic symmetry. However, their films grown on LaAlO_3 $\langle 100 \rangle$ shows cubic symmetry. The (002) peak shows a monotonic increase in lattice parameter from 3.87 to 3.94 Å with increasing Ru doping. The x-ray pattern (Fig. 1) shows epitaxial growth of Ru-substituted films on the LaAlO_3 substrates.

Magnetization curves for bulk $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ are

FIG. 1. X-ray diffraction of $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ for $x = 0, 0.05$, and 0.1 thin films grown by PLD on LaAlO_3 $\langle 100 \rangle$ substrates. Note the systematic increase in c parameter (002 reflection) with increasing Ru doping.

FIG. 2. Temperature dependence of the magnetization (at $H=200$ Oe) of $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ above room temperature in the doping range $0 \leq x \leq 0.15$.

shown in Fig. 2. The M vs T curves indicate a monotonic decrease in T_c , from 365 K for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (LSMO) to 335 K for $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{0.85}\text{Ru}_{0.15}\text{O}_3$ (For $x=0.1$ and 0.15 , a shoulder was seen in M vs T curve.) This is possibly due to instrumental error and not due to phase separation since our x-ray results show single phase without any impurity phase within the x-ray resolution of about 2%. The Curie temperature for the parent LSMO agrees well with the reported T_c values. Note the unusual doping effect of Ru which shows a very marginal decrease in T_c for doping upto 15% of Ru (ΔT_c is only around 35 K which is marginal). A large decrease in T_c in other cases, for example; doping of Al^{3+} , Fe^{3+} , and Ti^{4+} has been argued to have direct effect on the magnetic ordering. The positive influence of Ru doping on magnetic ordering could be interpreted based on the mixed valence states of Ru, as RuO_2 , RuO_3 , Ru_2O_3 etc. Although similar effects due to variable states has been observed recently by Raveau *et al.* on Cr and Co doping in $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ it should be noted that Cr and Co ions aid only in the insulator metal transition and not in the charge transfer mechanism. A rapid disappearance of the charge ordering has been observed for doping as small as $x > 0.02$ for Cr and Co. Ru substitution on the other hand stabilizes magnetic ordering upto 15%. This can be attributed to the $4d$ metal character of Ru. It is now fairly well understood that the $3d$ electrons are more localized compared to $4d$ electrons. Therefore exchange interaction between Mn–O–Ru could be favored much more than any other transition metals. The presence of variable oxidation state of Ru is evident from the x-ray photoelectron spectrum (Fig. 3) of the Ru substituted bulk samples. The peaks corresponding to 483.0 and 486.2 eV suggests the presence of a possible redox couple involving $\text{Ru}^{3+}/\text{Ru}^{4+}$. This further suggests that an interplay of a mixed Zener pair such as $\text{Mn}^{3+}/\text{Mn}^{4+}$ – $\text{Ru}^{3+}/\text{Ru}^{4+}$ could be decisive in the charge ordering.

Figure 4 shows resistivity versus temperature plot for the parent $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ film and the Ru substituted film, $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{0.9}\text{Ru}_{0.1}\text{O}_3$. Although ferromagnetic ordering occurs well above the room temperature, R vs T plot for the bulk samples show a very broad transition and the metal-

FIG. 3. X-ray photoemission spectroscopy (XPS) spectrum showing variable oxidation state for the Ru ($x=0.1$) bulk samples. The peaks corresponding to 483.0 and 486.2 eV suggests the presence of a possible redox couple involving $\text{Ru}^{3+}/\text{Ru}^{4+}$.

insulator transition occurs below 300 K. This is attributed to the role of the grain boundaries. However, upon subsequent annealing at elevated temperatures, well sintered pellets do show a M–I transition in accordance with the magnetic ordering temperature. The as-grown films of LSMO and Ru substituted films also show the same semiconducting behavior. In order to overcome this discrepancy, which could occur either from the enhanced role of grain boundaries or from loss of oxygen, the laser targets were sintered with 3% Ag_2O , to promote O_2 saturation of oxygen in the films during growth and annealing. Silver gets oxidized to AgO during laser ablation and during film growth AgO dissociates yielding its oxygen to the $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ films. It is well known that addition of Ag_2O to bulk $\text{YBa}_2\text{Cu}_3\text{O}_7$ and self doped $\text{La}_{1-x}\text{MnO}_3$ increases the oxygen content in the

FIG. 4. Temperature dependence of the resistivity at $H=0$ and 1 T of 3% Ag doped $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$ ($x=0.1$) film. Inset shows the temperature dependence of the resistivity at $H=0$ and $H=1$ T for parent $x=0$ and $x=0.1$ without Ag doping (full symbol: $H=0$, empty symbol: $H=1$ T).

YBCO and $\text{La}_{0.7}\text{MnO}_3$ film, respectively.^{8,9} Consequently, 3% Ag containing LSMO and Ru substituted LSMO films showed a metal-insulator transition corresponding to the ferromagnetic ordering. In summary we have shown for the first time the exceptional ability of Ru to stabilize magnetic ordering in the $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{1-x}\text{Ru}_x\text{O}_3$. It should be possible to apply such an effect to other perovskite manganites to evaluate the actual role played by Ru in ferromagnetism and to understand double exchange mechanism in mixed Zener pairs like $\text{Mn}^{3+/4+}$ - $\text{Ru}^{3+/4+}$.

Angle-resolved magnetic and transport properties of $\text{Pr}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ thin films

J. Wolfman,^{a)} W. Prellier, Ch. Simon, and B. Mercey

Laboratoire Crismat, UMR CNRS 6508, ISMRA, Bd du Juin 14050, Caen cedex, France

In this communication, the variation of the resistance and of the magnetization with respect to the angle between the applied magnetic field and the substrate normal is discussed for a $\text{Pr}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ thin film at 30 K. An angular hysteresis is observed for these properties and this behavior is correlated with the magnetic domain wall motion. It is shown that the number of domain walls is controlled through the rotation of the applied magnetic field, and that these domain walls play an important part in the colossal magnetoresistance behavior of these films. Furthermore, a model describing the reversal of the magnetization with the rotation of the magnetic field has been developed. This model enables one to extract the dependence of the resistance upon the direction of the magnetization with respect to the crystalline axis. © 1998 American Institute of Physics. [S0021-8979(98)52511-X]

Manganese perovskites exhibiting colossal magnetoresistance (CMR) have drawn large interest these last few years, particularly for the realization of thin films with technological applicability.^{1,2} However, the microscopic mechanism of CMR is not clearly established. The double exchange (DE) interaction,³ which has been classically involved to explain CMR, relates the hopping rate of an e_g hole between two Mn sites to the angle between the respective moments of these Mn sites. Yet this interaction does not consider the direction of the moments with respect to the hopping direction (i.e., the local current direction) nor to the crystalline direction. Eckstein *et al.* have shown⁴ that the resistivity of a $\text{La}_{0.66}\text{Ca}_{0.33}\text{MnO}_3$ thin film depends upon the angle between the in-plane applied magnetic field and the current direction. They have compared this effect to the anomalous magnetoresistance (AMR) observed in metal thin films. However, this resistivity variation could also be related to the direction of the Mn moments with respect to the crystalline axis. In order to investigate this possibility, we have carried out magnetic and transport measurements on a $\text{Pr}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ thin film, while varying the direction of the applied magnetic field, \mathbf{B} , with respect to the crystalline axis, and keeping \mathbf{B} perpendicular to the current direction.

In situ annealed $\text{Pr}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ thin films were grown on LaAlO_3 substrates by pulsed laser deposition. The microstructure has been investigated by x-ray diffraction and transmission electron microscopy (TEM), and is discussed, with respect to the growth conditions, in details elsewhere.⁵ TEM has evidenced that the films crystallize epitaxially and with the space group Pbnm. The growth axis is in the $[110]$ direction ($a \approx b \approx \sqrt{2} a_p$) and the c axis is in the plane of the film ($c \approx 2a_p$). The pseudocubic structure of this material, identical to that obtained by rf sputtering,⁶ gives rise to the coexistence of domains with perpendicular c axis. The thickness of the films was determined to be 7000 Å (mechanical probe measurement).

Electrical measurements, registered by the four-probe method along the $[100]$ direction of LaAlO_3 , evidence a transition from an activated state ($E_a = 108$ meV) to a metallic state at $T = 240$ K as the temperature is decreased. This transition is correlated with the onset of ferromagnetic ordering at $T_c = 252$ K. These temperatures are comparable to those observed in bulk materials ($T_c = 259$ K).⁷ A magnetic field of 70 kG, applied in the plane of the film and perpendicular to the current I , gives rise to a CMR ($R_0/R_{70\text{ kG}}$) of 400% at $T = 200$ K. The spontaneous magnetization of this composition has been reported to be 564 emu/cm³ at 5 K (neutron diffraction⁷), i.e., locally, the magnetic moments are almost completely polarized. The maximum magnetization measured was 426 emu/cm³ in a magnetic field of 17 kG at 5 K, evidencing the existence of magnetic domains.

Magnetic and transport measurements presented below, were made at a constant field modulus B and at 30 K. The direction of \mathbf{B} was varied inside a plane containing the substrate $[010]$ direction and the substrate normal ($\mathbf{B} \perp \mathbf{I}$). Θ_B , defined as the angle between the \mathbf{B} direction and the substrate normal, was varied from -90° to $+90^\circ$. Furthermore, transport measurements were made as Θ_B was varied back to -90° .

The Θ_B dependence of the resistance and of the magnetization are given in Figs. 1 and 2, respectively, and will be discussed together. It should be noted that the measured magnetic moment, herein called M_{\parallel} (see Fig. 2), is the component of the global moment \mathbf{M} along the \mathbf{B} direction. Thus, if Θ_M is defined as the angle between \mathbf{M} and the substrate normal, $M_{\parallel} = M \cos(\Theta_M - \Theta_B)$. The observed decrease of M_{\parallel} at low fields [Fig. 2(b)] results from two effects. First, as \mathbf{M} rotates out of the plane of the film, the internal field H_i decreases due to the increase of the demagnetizing field H_d [$H_d = 4\pi M \cos(\Theta_M)$], leading to a decrease of M . Second, as \mathbf{B} rotates out of the plane, \mathbf{M} tends to follow \mathbf{B} , but is delayed with respect to \mathbf{B} owing to H_d , increasing $\Theta_M - \Theta_B$. At 600 G [Fig. 1(a)], the resistance presents a large hysteresis and two maximum. For $B = 2500$ G the hysteresis tends to be restricted around $\Theta_B = 0^\circ$. For a further B in-

FIG. 1. Θ_B dependence of the resistance in an applied magnetic field equal to (a) 600 G, (b) 2.5 kG, (c) 4.5 kG, (d) 5.5 kG, (e) 12.5 kG, (f) 20 kG, and (g) 60 kG.

crease [Figs. 1(c) and 1(d)], a hysteresis develops for higher Θ_B , the resistance maximum moving toward $\Theta_B=0$. The maximum of resistance are expected to arise as \mathbf{M} is perpendicular to the substrate (maximum H_d). The fact that they do not appear for $\Theta_B=0$ denotes that \mathbf{M} is delayed with respect to \mathbf{B} . A decrease of the resistance is also observed for $B \geq 4500$ G around $\Theta_B=45^\circ$ and 0° . For $B > 7000$ G, the resistance is reversible with respect to Θ_B . The reversibility (or the irreversibility) of $R(\Theta_B)$ upon \mathbf{B} can be accounted for by the magnetic domain wall motion. The $M(B)$ curve at 30 K with $\mathbf{B} \parallel$ to the film (not shown) indeed presents hysteresis of the magnetization for $B < 3500$ G. This hysteresis, due to domain wall motion, is thus reversible (irreversible) for $B > 3500$ G ($B < 3500$ G). In the out-of-plane magnetic field

FIG. 3. H_i dependence of the resistance extracted from the $R(\Theta_B)$ curves (solid lines) in an applied \mathbf{B} of (from bottom to top): 20 kG, 15 kG, 12.5 kG, 10.5 kG, 8.5 kG, 7.5 kG. In insert, $B=7.5$ kG. Also shown in $R(H)$ while H is ramped from 0 G to 70 kG and back to 0 G (lines with dots) in the plane of the film.

set up described above, H_d is about 4000 G for $B=7500$ G and $\Theta_M=0$ [see Fig. 2(b) for $\Theta_B=-90^\circ$], leading to an internal field of about 3500 G.

To establish the correlation between Θ_M and Θ_B at a fixed applied field, we have developed a model describing $\mathbf{M}(\Theta_B)$, which takes into account the applied field \mathbf{B} , the demagnetizing field \mathbf{H}_d , and the magnetocrystalline energy. The magnetization was assumed to be homogeneous to define H_d . Furthermore, we assumed that \mathbf{M} is pointing in the direction of the internal field \mathbf{H}_i ($\mathbf{H}_i = \mathbf{B} + \mathbf{H}_d$). The total energy is minimized in a step-by-step calculation, varying Θ_B . This model does not account for hysteresis behavior, and was then used for $B > 7000$ G. A detailed description of the model will be published elsewhere. The calculations result in a good quantitative agreement as exemplified by that displayed in Fig. 2 (solid lines). Thus, the variation of Θ_M and H_i as functions of Θ_B can be calculated by this model.

We have represented the variation of the resistance extracted from the $R(\Theta_B)$ curves as a function of H_i in Fig. 3 (the minimum H_i is for $\Theta_B=0$ and corresponds to the maximum H_d). Figure 3 also displays the variation of the resistance upon a magnetic field \mathbf{H} [$R(H)$], while the latter is applied along the [010] direction of the substrate (i.e., $\mathbf{H}_i = \mathbf{H}$), and ramped from 0 to 70 kG and back to 0 G. It appears that the resistance extracted from the $R(\Theta_B)$ curves are much less sensitive to H_i than is $R(H)$. $R(H)$ is hysteretic, resulting from a different magnetic state before and after the application of a 70 kG field: the number of magnetic domains can be assumed to be different, giving rise to an increase (decrease) of the scattering rate of the carriers as the number of domain walls increases (decreases). The $R(H_i)$ curves deduced from the $R(\Theta_B)$ curves are reversible and join the two branches of the $R(H)$ curve as H_i varies. This indicates a nucleation of magnetic domains as \mathbf{M} rotates from $\Theta_M=0$ to $\Theta_M=90^\circ$. The dependence of the resistance upon H_i (see the inset of Fig. 3) results from the onset of two

antagonist effects. As \mathbf{M} rotates from $\Theta_M = 90$ to $\Theta_M = 0$, \mathbf{H}_i decreases, giving rise to a slight decrease of \mathbf{M} . From the DE point of view, decreasing \mathbf{M} leads to a decrease of the hopping rate, i.e., an increase of the resistance. However, it has been shown that, during the same rotation ($\Theta_M = 90 - \Theta_M = 0$), the number of domain walls decreases, tending to decrease the resistance. The competition between the decrease of both \mathbf{M} and the number of domain walls explains the not monotonous variation of R upon \mathbf{H}_i . The $R(\Theta_B = \pm 90)$ values are systematically higher than the $R(H)$ values from the upper branch (field increasing) and can be accounted for by the existence of a larger number of magnetic domain walls, since the $R(\Theta_B)$ curves were registered one after the other, increasing \mathbf{B} . Since R is not monotonous in \mathbf{H}_i , it appears that \mathbf{H}_i is not the primary factor in determining $R(\Theta_B)$.

To investigate the Θ_M dependence of the resistance, we have plotted in Fig. 4 the normalized $R(\Theta_M)$ curves for four different \mathbf{B} . These curves are field independent for $\Theta_M \geq 60^\circ$ and diverge for lower Θ_M values. Because of the co-existence of magnetic domains, there is some deviation of the local magnetic moment direction (Θ_m) with respect to the global moment direction (Θ_M); Θ_M is then the spatial average value of the Θ_m . In a plot displaying the total energy as a function of Θ_M for a fixed Θ_B , there appears two local minima with a difference energy ΔE . The probability of a local moment direction to shift from one local minimum to the other is related to ΔE : the lower ΔE is, the more easily Θ_m shifts (ΔE has to be compared to the energy cost E_n of a domain nucleation). The calculation shows that as Θ_B decreases, ΔE decreases and minimizes for $\Theta_B = 0$. Local magnetic direction fluctuations are then favored by a decrease of Θ_B (which implies a decrease of Θ_M). For a fixed Θ_B , ΔE depends also upon \mathbf{B} : the higher \mathbf{B} is, the higher ΔE is. In the field independent part of the $R(\Theta_M)$ curves, the deviations of Θ_m around Θ_M are negligible, which implies that ΔE is large compared to E_n . For $\Theta_B < 60^\circ$, the $R(\Theta_M)$ curves separate, and their different shapes are thus due to different ΔE (for a fixed Θ_B and Θ_M) owing to the different applied magnetic fields. If we assume that deviations of Θ_m around Θ_M are negligible for $\mathbf{B} = 60$ kG (i.e., $\Theta_M \cong \Theta_m \cong \Theta_B$), we can describe the real dependence of the resistance

FIG. 4. Θ_M dependence of the resistance extracted from the $R(\Theta_B)$ curves, normalized to $R(\Theta_B = -90^\circ)$, in an applied \mathbf{B} of: 7.5 kG (triangles), 12.5 kG (circles), 20 kG (solid line) and 60 kG (squares).

upon \mathbf{M} as follows: the resistance is maximum when \mathbf{M} is in the film plane and is minimum when \mathbf{M} is perpendicular to the film. At lower fields, the fluctuations of Θ_m around Θ_M imply the creation of magnetic domain walls which take part in the observed increase of the resistance around $\Theta_B = 0$ (inset of Fig. 3). Finally, it has been shown that AMR is not the only anisotropic effect involved in CMR thin films; the resistance also depends upon the direction of the magnetization with respect to the crystalline axis.

Supercurrent suppression by the injection of spin-polarized quasiparticle current from a ferromagnet into a superconductor is demonstrated in $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}/\text{SrTiO}_3/\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_{3-\delta}$ junctions at 77 K. Negative current gains as large as 35 have been observed. The magnitude of the effect depends on the net polarization of the injection current, film resistivities, barrier microstructure, and injection geometry. Fabrication of the junctions is discussed in terms of optimizing these parameters for maximum supercurrent suppression. © 1998 American Institute of Physics.

[S0021-8979(98)31911-8]

I. INTRODUCTION

Trilayer ferromagnet-chemical barrier-high temperature superconductor junctions, called spin injection devices, are a new direction in superconducting transistors. The spin injection devices operate by the disruption of Cooper pair formation in the superconductor film due to the injection excess spin state quasiparticles from the ferromagnetic film. A small injection current can suppress a large supercurrent, producing a large negative current gain.

The spin injection device is the natural extension of earlier work on injection of spin-polarized currents into normal metals¹ and low temperature superconductors,² and unpolarized quasiparticle injection into superconductors.³ However, the possibility of transistorlike devices based on spin-polarized quasiparticle injection was only recently investigated in a study of permalloy/Au/ $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ junctions.⁴ All-oxide spin injection devices consisting of $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3/\text{La}_2\text{CuO}_4/\text{DyBa}_2\text{Cu}_3\text{O}_7$ (Ref. 5) and $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_{3-\delta}/\text{SrTiO}_3/\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (Ref. 6) junctions have since been investigated.

The potential advantages of superconducting transistors have inspired many different types of devices.⁷ None has yet to exhibit all of the necessary characteristics for bridging the gap between research tool and useful application. Each fails in either reproducible fabrication, gain, power handling, or speed. Spin injection devices offer the potential for increased speed and gain compared to existing devices.

Spin injection devices are also an exciting system in which to study nonequilibrium superconductivity and spin dynamics. It should be possible to measure the spin diffusion length of a superconductor simply by varying the film thickness in these devices. Devices with film thickness greater than the spin diffusion length would exhibit less supercurrent suppression because spin flip scattering would decrease the net polarization of the injected quasiparticles. For anisotropic

superconductors such as $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$, the spin diffusion length could be measured along each axis independently by changing the injection direction.

The suppression of supercurrent by spin injection must be unambiguously demonstrated before spin injection devices can become either useful superconducting transistors or an arena for the investigation of nonequilibrium superconductivity. In this article, supercurrent suppression in a $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}/\text{SrTiO}_3/\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_{3-\delta}$ trilayer junction is demonstrated, and the fabrication and material issues necessary for producing the optimum spin injection effect are outlined.

II. PROCEDURE

$\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_{3-\delta}$ (LSMO) films were deposited on (100) SrTiO_3 single crystal substrates by pulsed laser deposition (PLD). Typical deposition conditions were: a 750 °C substrate temperature, a 200 mT O_2 atmosphere, and 2 J/cm² laser fluence. The resultant 1000 Å thick films were patterned into 100–150 μm wide microbridges. The patterning was performed using wet-etch photolithography, with a 100% HCl etch solution. After patterning, the LSMO films were annealed at 800 °C to remove surface impurities and lower the contact resistance.

The insulating barrier and superconducting films were deposited sequentially through a rectangular shadow mask by PLD. The barrier was either SrTiO_3 (STO) or CeO_2 , 50–400 Å thick, deposited at 750 °C in 300 mT O_2 . The superconductor was $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (YBCO), 500–1000 Å thick, deposited at 790 °C in 320 mT O_2 . The YBCO was patterned into a microbridge by wet-etch photolithography, to produce a YBCO-LSMO cross with a square junction area of 10⁴ μm². A schematic of the device is shown in Fig. 1.

The suppression of YBCO supercurrent was determined by measuring the transport critical current at 77 K as a function of current through the junction.

^{a)}Electronic mail: rms@ccf.nrl.navy.mil

FIG. 1. Junction schematic.

III. RESULTS

The suppression of critical current in a YBCO/400 Å STO/LSMO device is shown in Fig. 2. For an injection current (I_{inj}) of 2 mA, the critical current of the YBCO (I_c) is reduced from 97 to 27 mA.

The current gain of the device is obtained from the slope of the plot of critical current versus injection current (Fig. 3), $\Delta I_c / \Delta I_{inj}$. For the 400 Å barrier device, the gain was -35 . In comparison, the suppression of critical current by resistive heating due to a current along the axis of the microbridge in the LSMO film, i.e., no injection, results in a gain of -6 .

IV. DISCUSSION

The key issue for operation of the spin-polarized quasiparticle injection devices is the delivery of highly polarized injection current into a narrow region of the superconductor. This provides the greatest density of excess spin state quasiparticles to suppress the superconductivity. Suppression of the superconductivity by dynamical effects not related to spin-polarized injection, such as resistive heating, must be minimized or eliminated to obtain a clear interpretation of the spin injection effect. As shown in Fig. 2, however, both spin-polarized injection and resistive heating contribute to

FIG. 2. Voltage vs $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ supercurrent. The critical current decreases from 97 mA for no injection current to 27 mA for an injection current of 2 mA.

FIG. 3. Critical current vs injection current.

the observed negative current gain (Fig. 3). Careful consideration of the materials processing and device design parameters is needed so that the spin injection effect may be quantified, understood, and optimized.

There are several ways in which the spin-polarized current can be injected. Depending on the particular insulating barrier thickness and microstructure, the injection will occur by tunneling, capacitive coupling, defect mediated processes such as pin holes or conduction at grain boundaries, or some combination of these processes. Only tunneling, pin holes, or grain boundary current will preserve a high degree of spin polarization; capacitive coupling does not preserve the polarization because no current flows from the ferromagnet to the superconductor. For thick barriers (100 Å), tunneling is not significant, so the spin-polarized injection current must be defect-mediated transport. For very thin barriers (<100 Å), there may be both pin hole injection current and tunneling injection current. For the 400 Å thick barrier device, the asymmetric s -shape of the barrier current-voltage (I - V) curve (Fig. 4) indicates that the transport is defect-mediated, possibly due to pin holes and interface defects.

The maximum suppression will occur when the current density of the spin-polarized quasiparticles is highest. High injection current densities relative to the YBCO supercurrent can be achieved by minimizing the width of the LSMO microbridge relative to the YBCO microbridge width. Increasing the injection current to obtain high current density is not desirable, because Joule heating from a large current could raise the temperature of the superconductor, and lower the critical current. For this reason we have adopted the YBCO/STO/LSMO cross-stripe sandwich geometry. The junction is

FIG. 4. Current vs voltage for the trilayer junction.

constrained to a rectangle defined by the overlap of the LSMO and YBCO microbridges. No other contact is made between the LSMO and YBCO, except potentially along the LSMO step edges, if the barrier does not provide uniform coverage. The step edges must be very gradual to provide uniform coverage with very thin barriers. The slope of the wet-etched LSMO edge measured by profilometry was $0.1 \mu\text{m}/10 \mu\text{m} = 0.01$, sufficiently gradual to uniform coverage by the barrier.

The insulating barrier has two functions—to chemically protect the superconductor and to spread the injection current so that it can suppress the conductivity uniformly. If the superconductor itself is nonuniform, suppression will occur preferentially along weak links. Only an insulating barrier can ensure that the injection current reaches the weak links; a metallic barrier would allow the injection current to find the path of least resistance around the weak links. It is possible for the device to operate by injection through a distribution of pin holes in the barrier into a network of weak links, and because the area of the pinholes is small compared to the junction area the current density could be further increased.

The maximum current gain due to spin injection will occur in devices with 100% spin-polarized injection, but 100% spin-polarized injection current is not required in order to observe a spin injection effect.⁴ No disruption of the superconductivity will result from minority spin state quasiparticles, assuming they form Cooper pairs with majority spin state quasiparticles and the energy released in pair formation is removed from the superconductor in the form of phonons. The remaining excess majority spin state quasiparticles will continue to suppress the superconductivity. In this case, a larger injection current would be required to observe the suppression because a reduced fraction of the quasiparticles would be available to suppress the superconductivity.

The net polarization of the injection current in the superconductor depends on the net polarization at the ferromagnet and the number of spin flip scattering events that occur between the ferromagnet and superconductor. Complete polarization of the injection current is only possible if the injection source is 100% polarized, and no spin flip scattering events occur in the barrier, or at the LSMO-STO and STO-YBCO interfaces. Even if the injection current is 100% polarized at the source, a reduction in the spin polarization could occur at the film interfaces as a result of spin glass formation due to interdiffusion or oxygen vacancies. Spin flip events at bulk defects in the barrier are also possible.

Because spin scattering cannot be completely eliminated in the barrier and at interfaces the injection current in the

superconductor will never have 100% net polarization. However the polarization is maximized through the use of a highly polarized injector, such as LSMO, and a thin chemical barrier. In earlier spin injection experiments, the injection source was permalloy, which provided a maximum polarization of 40%, which was sufficient to observe supercurrent suppression. Half metallic ferromagnets, such as CrO_2 or LSMO and other rare earth manganites, are ideal choices for injectors because they carry 100% spin-polarized current, and they are more compatible for growth and processing with YBCO than traditional metal ferromagnets because of their oxide structures.

A major obstacle to quantifying the suppressive effect of the spin polarization of the injected current is the similar suppression produced by simple resistive heating. From the current gain plotted in Fig. 3, it is clear that heating is a significant effect in the junction with a 400 \AA thick barrier, even when the current is restricted to the LSMO. To lower the heating, the input power must be lowered. This can be achieved by decreasing resistances of the barrier, the injector, and the interfaces. The input power could also be lowered by decreasing the injector microbridge width, producing higher current density at lower injection currents.

V. SUMMARY

The control of superconductivity in $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ by injection of spin-polarized quasiparticle current offers the possibility of a new type of superconducting transistor. Supercurrent suppression has been demonstrated in $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}/\text{SrTiO}_3/\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_{3-\delta}$ junctions. Current gains as large as -35 have been observed. The materials and fabrication issues that affect the size of the observed gain, including the mode of current injection, the polarization of the injection current, the structure of the barrier, device geometry, and resistive heating have been investigated.

The magnetization and resistivity of single crystals of the ferromagnetic compound $\text{Sr}_{14}\text{MnSb}_{11}$ are measured as functions of magnetic field, temperature, and crystal orientation. The uniform magnetic susceptibility is used to identify $T_C = 39$ K. The ferromagnetic state is found to have a hard axis (c axis) anisotropy. The resistivity data place the compound in the class of colossal magnetoresistance (CMR) materials such as Ca-doped LaMnO_3 . The data are also compared to the related CMR material $\text{Eu}_{14}\text{MnSb}_{11}$. © 1998 American Institute of Physics.

I. INTRODUCTION

Recently, we have shown that the compounds $\text{Eu}_{14}\text{MnSb}_{11}$ ¹ and $\text{Eu}_{14}\text{MnBi}_{11}$ ² can be classified as colossal magnetoresistance (CMR) materials.³ In CMR materials, the magnetoresistance is much larger than for simple metallic ferromagnets, such as Fe and Ni, and is largest in a region of temperature where there are large ferromagnetic spin fluctuations and T_C appears to mark a metal-insulator transition. These two compounds are part of a large set of isostructural compounds with the formula $\text{A}_{14}\text{MPn}_{11}$ ($\text{A} = \text{Ca}, \text{Sr}, \text{Ba}, \text{Eu},$ or Yb , $\text{M} = \text{Al}, \text{Ga}, \text{In},$ or Mn , and $\text{Pn} = \text{P}, \text{As}, \text{Sb},$ and Bi).⁴ They crystallize in the space group $I4_1/acd$ and have a tetragonal unit cell with eight formula units in the cell. This series of compounds with $\text{M} = \text{Al}, \text{Ga},$ or In belong to the class of Zintl compounds.⁵ Zintl phases are composed of electropositive ions which donate electrons to the more electronegative components forming covalent bonding networks or closed shell anions. Because Zintl compounds are salts, the main group Zintl phases are all expected to be insulators (possibly with small band gaps); in particular, the main group compounds isostructural to $\text{Sr}_{14}\text{MnSb}_{11}$ are all known⁶ to be semiconducting. Since all of these phases are isostructural, one might expect the Mn compounds to be semiconductors with local moments on the Mn. However, most of the compounds containing the transition metal Mn are conducting, have ferromagnetic exchange coupling, and display an intimate connection between the conductivity and the magnetism. The conductivity is unexpected because the materials are salts made up of isolated cations and isolated anion complexes and conducting paths are not apparent. In addition, the high magnetic transition temperatures are unexpected because the Mn^{3+} ions, which are tetrahedrally coordinated with four Pns, are quite isolated from their neighboring Mn ions, about 11 Å interionic spacing for the Mn.

The importance of the Mn to both the magnetism and the conductivity is illustrated in an examination of the gross properties of the series, of which the alkaline earth contain-

ing compounds have been studied^{7,8} in the greatest detail. There is a metal-insulator (M-I) boundary between the $\text{Pn} = \text{As}$ compounds [semiconductors with resistivity $\rho(T = 300 \text{ K}) > \text{few thousand } \mu\Omega \text{ cm}$ and negative $d\rho/dT$] and the $\text{Pn} = \text{Sb}$ compounds [semimetals with $\rho(T = 300 \text{ K})$ of order $1000 \mu\Omega \text{ cm}$ but $d\rho/dT$, still slightly negative at high T]. The $\text{Pn} = \text{Bi}$ compounds are the most conducting [$\rho(T = 300 \text{ K})$ of order $100 \mu\Omega \text{ cm}$ and $d\rho/dT$, positive] of all but can still be considered to be near a M-I boundary. Near neighbor Mn spins in the conducting compounds all have fairly strong ferromagnetic exchange coupling and order at temperatures between 10 and 100 K. The Mn spins in the semiconducting As compounds have an exchange coupling which is quite weak (Curie-Weiss $\theta < 0.5 \text{ K}$); however, under hydrostatic pressure even these As compounds have Mn moments coupled ferromagnetically⁹ with ($-\theta > 10 \text{ K}$). In this article we examine the magnetization and resistivity of one of these compounds, $\text{Sr}_{14}\text{MnSb}_{11}$, and compare with $\text{Eu}_{14}\text{MnSb}_{11}$.

II. DETAILS OF THE EXPERIMENTS

The measurements were performed on needlelike ($0.1 \text{ mm} \times 0.1 \text{ mm} \times 1 \text{ mm}$) single crystals with the needle long axis coincident with the tetragonal c axis. These needles were grown from the elements by loading stoichiometric quantities of the elements into Ta tubes in a drybox. The tubes are welded shut and then sealed in quartz tubes under vacuum. The sample is then placed in a zone furnace in a temperature gradient of about 10°C/cm at an average $T = 1000\text{--}1250^\circ\text{C}$ for several days. The sample was examined in a drybox and appropriate needles were removed for measurement.

The magnetization data were acquired with a quantum design superconducting quantum interference device (SQUID) magnetometer with a temperature range of $2 \text{ K} < T < 300 \text{ K}$ and a magnetic field range of $-5 \text{ T} < H < 5 \text{ T}$. A single needle shaped crystal was mounted at the center of an Al rod about 12 cm long which is then sealed under vacuum inside a thin quartz tube. The needle axis was oriented either parallel to the applied magnetic field (H_{para}) or perpendicular (H_{perp}). The absolute value of the magnetiza-

FIG. 1. Volume magnetic susceptibility (emu/cm^3) of a single crystal of $\text{Sr}_{14}\text{MnSb}_{11}$ as a function of the temperature for two orientations of the applied field in relation to the c axis of the crystal.

tion is determined by the volume of the crystal which is a quantity we cannot measure well. Given this problem we have chosen to normalize the magnetization data so that the saturation magnetization, M_s , at the lowest T is appropriate for the $4 \mu_B$ present on the Mn^{+3} ion. This is consistent with M_s for the powder samples we have measured^{6,7} in the past. The electrical resistivity measurements were performed in the same instrument in the same orientation of the crystal with the same ranges of temperature and field. Four leads were attached along the length of the crystal with silver paint for the resistivity measurements. Because of the geometry of the crystal the current, I , is always applied along the c axis of the tetragonal cell but magnetic field may be applied either parallel or perpendicular to I .

III. DC MAGNETIZATION AND SUSCEPTIBILITY

In Fig. 1 we show χ as a function of T both for H_{para} to the c axis and H_{perp} . We will call these χ_{para} and χ_{perp} , respectively. The data with H_{para} do not need a demagnetization correction and the data for H_{perp} have not been corrected for demagnetization because the cross-sectional area is not simple and is not constant over the length of the sample. One sees that there is a very strong anisotropy with the c axis being a magnetic hard axis. Note that this crystal-line anisotropy dominates the shape anisotropy of the needle. This is in contrast to $\text{Eu}_{14}\text{MnSb}_{11}$ for which the c axis was an easy axis. One can identify $T_C = 39$ K, from these data, as the temperature where there is a kink in the measured $\chi_{\text{perp}}(T)$. If the assumption is made that χ_{perp} is demagnetization limited below T_C then the demagnetization factor is 0.2 which is probably reasonable but slightly larger than the expected value of 0.16 for the thin wire geometry. The irregular shape of the crystal, the large demagnetization factor, and the scatter in the magnetic moment data on these very tiny single crystals make a detailed analysis of critical phe-

FIG. 2. Magnetic hysteresis loops at $T = 5$ K for two orientations of a single crystal of $\text{Sr}_{14}\text{MnSb}_{11}$.

nomena in these samples problematic and we do not attempt it here. In Fig. 2 we show the hysteresis loops for H_{para} and H_{perp} . Again, one sees the results of the magnetically hard c axis.

IV. ELECTRICAL RESISTIVITY

Figure 3 shows the measured resistivity as a function of T and H applied perpendicular to the c axis, that is, H is applied along an easy direction. The zero field resistivity rises as T is decreased then drops at or near T_C in a manner which is roughly similar to many other CMR materials³ including $\text{Eu}_{14}\text{MnSb}_{11}$. This behavior is generally characterized as a semiconductor to metal transition which occurs at or near T_C . This characterization is made clearer in Fig. 4

FIG. 3. Resistivity of $\text{Sr}_{14}\text{MnSb}_{11}$ as a function of temperature for six values of magnetic field applied in the easy direction (H_{perp}).

FIG. 4. Natural logarithm of the resistivity of single crystals of $\text{Sr}_{14}\text{MnSb}_{11}$ and $\text{Eu}_{14}\text{MnSb}_{11}$ as a function of $1000/T$. Each of these compounds has an activated conductivity at high temperatures.

which shows that the high temperature zero field resistivity of $\text{Sr}_{14}\text{MnSb}_{11}$ follows, at highest T , the simple form for activated conduction. This figure also shows the data for $\text{Eu}_{14}\text{MnSb}_{11}$ which obey the simple form for T nearly to T_C . We note that the values of the activation energy one gets from Fig. 4 are quite small (few meV). It seems likely that these are not band gap energies but the results of electron-electron correlations as in coulomb gap materials and/or Kondo insulators. In any case, this form is inconsistent with variable range hopping conductivity⁴ seen in the La manganites. Variable range hopping is not expected in this family of Zintl compounds because they are ordered stoichiometric compounds.

V. SUMMARY

We have shown that the compound, $\text{Sr}_{14}\text{MnSb}_{11}$, has a very large negative magnetoresistance in the vicinity of the Curie temperature. In addition, there appears to be a change from semiconductorlike behavior in the electron transport at high T to metallic behavior at low T to metallic behavior at low T . For these reasons, we place this compound in the class of CMR materials.

Highly smooth and particulate free relatively thick polycrystalline $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films out to 6 μm thick have been grown by shadowed pulse laser deposition at 30 Hz (248 nm, 500 mJ). Such films exhibited a low field and high field magnetoresistance as previously reported by a number of groups. Multilayer films made with alternating 8-nm-thick barium ferrite and 16-nm-thick $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ laminations exhibited the same high field response, but did not exhibit the low field magnetoresistance component. This is consistent with the low field component arising from intergrain scattering. Patterned films have been simultaneously deposited onto *R*-plane, *C*-plane, and polycrystalline alumina substrates. The films were postannealed at 750 K in 200 Torr O_2 for 45 min. The low field magnetoresistance was most pronounced for the single layer films made onto *C*-plane sapphire and then polycrystalline alumina substrates. The films exhibited a broad maximum in resistivity versus temperature at 162, 210, and 218 K for films grown onto *R*-plane sapphire, *C*-plane sapphire, and alumina substrates, respectively. Restricted grain size films made with $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ and barium ferrite laminations exhibited a single linear magnetoresistance response of $-0.43\%/k\text{Oe}$ for in plane applied fields of $\pm 10 k\text{Oe}$. © 1998 American Institute of Physics. [S0021-8979(98)45311-8]

I. INTRODUCTION

Although La-manganite bulk samples exhibit a large magnetoresistance at relatively low temperatures,¹ the narrowness of the transition region as a function of temperature, and the high multi-Tesla magnetic field values required for saturating the magnetoresistance have precluded applications. Over the last several years a number of groups have reported broadened transitions for polycrystalline films with enhanced low field magnetoresistance.²⁻⁵ The enhanced low field magnetoresistance in polycrystalline films has been attributed to either intergrain spin polarized tunneling,³ or to spin-dependent scattering of polarized electrons at the grain boundaries.⁵ An important attribute of the polycrystalline samples is that magnetoresistive response extends over a wide temperature range. Such a wide temperature response of the magnetoresistance is critical to the development of the La manganites for technological devices. The Sr substituted $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ for polycrystalline samples exhibits a broad transition with appreciable magnetoresistance in the vicinity of room temperature and consequently is attractive for magnetic sensor applications. For device applications it is also necessary that other materials such as soft magnetic films be deposited which exhibit compatible processing properties with the La manganites. This presents processing problems since oxide materials generally require relatively high processing temperatures compared to metallic magnetic films. In this article we demonstrate two things necessary for La-manganite device applications. One is that the low magnetic field response of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films can be controlled, and

linearized by using layered film strips. The low field magnetoresistance was made linear without changing the temperature of the resistance maximum by laminating the $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ deposit with highly resistive barium hexaferrite film layers. The second is that high magnetization and highly corrosion resistant $\text{Fe}_{0.8}\text{Co}_{0.2}$ films can be deposited in conjunction with the La manganites to provide magnetic flux paths as well as electrical contacts. In previous studies polycrystalline versus epitaxial films have been studied.⁴ In this study polycrystalline samples have been studied in which the intergrain coupling has been changed by laminating with resistive barium ferrite layers to isolate the grains. Single and multilayer films were made by pulsed laser deposition (PLD) that exhibit large differences in the temperature of the resistance maximum as well as different low field magnetoresistive responses.

II. EXPERIMENT

PLD utilizing a Lambda Physik 305Fi excimer laser has been used to deposit La-manganite films from a set of bulk compound targets. In addition, a multitarget carousel has been used in some cases to allow the alternate deposition of barium hexaferrite films in conjunction with La-manganite film layers. The films were deposited using a wavelength of 248 nm, pulse energy of 500 mJ, at 30 Hz, with an estimated pulse width of 15 ns. A shadow mask has been used to shield part of the substrate during the PLD process. In this manner the number of particulates reaching the substrate in and out of the shadow region could be observed. Very fine grained, $<300 \text{ \AA}$, highly (130) textured films were grown in 120 mTorr O_2 behind a shadow plate at an average rate of 6 $\text{\AA}/\text{s}$

^{a)}Electronic mail: fred_cadieu@qc.edu

FIG. 1. The normalized resistances measured in zero field for a set of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films simultaneously made onto *R*-plane sapphire, *C*-plane sapphire, and polycrystalline alumina substrates are shown as a function of temperature.

simultaneously onto *C*-plane, *R*-plane sapphire, and polycrystalline alumina substrates. The films discussed here were deposited using a substrate temperature of 750 °C in 120 mTorr of flowing oxygen. Low field magnetoresistance measurements were made using a standard four-terminal technique, and in other cases using FeCo sputtered film magnetic flux paths which also acted as the electrical connections to the La-manganite film strips. During the PLD deposition patterned La-manganite films have been directly deposited by using alumina contact masks to only expose a strip of the substrates. Film thicknesses, grain sizes, and the presence of particulates has been studied using a scanning electron microscope (SEM). Film compositions were determined by electron excited x-ray spectroscopy in the SEM. Magnetization measurements were made using a vibrating sample magnetometer.

As a means of making electrical as well as magnetic field circuit connections to La-manganite films, sputtered films of $\text{Fe}_{0.8}\text{Co}_{0.2}$ have been used in most cases. The sputtered $\text{Fe}_{0.8}\text{Co}_{0.2}$ films exhibited an in plane intrinsic coercivity of 18 Oe and a saturation flux density of 24 kG as determined by extrapolating the perpendicular to the plane measurements to the in plane saturation flux density. The FeCo films were diode sputter deposited in 17 mTorr Ar at 150 °C. A key feature of these FeCo sputtered films was their corrosion resistance which made it possible to reoxygenate La-manganite films without changing the electrical, magnetic, and appearance properties of the in-plane FeCo sputtered films.

III. RESULTS AND DISCUSSION

Figure 1 shows the resistance of strips of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films that were simultaneously deposited as masked strips onto *R*-plane sapphire, *C*-plane sapphire, and polished polycrystalline alumina substrates. The films were deposited at substrate temperatures of 750 °C in 120 mTorr O_2 using a stainless steel shadow between the target and substrates. The films were thus relatively particulate free and highly smooth. The resistances shown in the figure are normalized to the

FIG. 2. The normalized resistances measured at 293 K are shown as a function of in-plane applied magnetic field for the same set of substrates as shown in Fig. 1.

maximum value at the resistance maximum. The temperature of the resistance maximum and strip resistance at the maximum were for *R*-plane sapphire 162 K and 3.58 kΩ, for *C*-plane sapphire 218 K and 2.41 kΩ, and for polycrystalline alumina 210 K and 1.48 kΩ. The resistance maximum for the films deposited onto *C*-plane and polycrystalline alumina occurs at a temperature of 56 and 48 K higher, respectively, than that for the *R*-plane substrate. Figure 2 shows the low field in plane magnetoresistance of these films as measured at 293 K. The resistances are shown normalized to the zero field response to illustrate the contrasting behavior of the *R*-plane sapphire, *C*-plane sapphire, and alumina substrates. The strip resistances at 293 K, respectively for *R*-plane sapphire, *C*-plane sapphire, and polycrystalline alumina were 2.01, 2.06, and 1.28 kΩ. The film deposited onto the polycrystalline alumina substrate exhibited a resistance of only 62% of that of the *C*-plane sapphire substrate sample. The low field response of the inexpensive polycrystalline alumina substrate sample is comparable to that of the *C*-plane sapphire substrate sample. No evidence for any hysteresis in the magnetoresistance was observed for any of these samples in

FIG. 3. Room temperature hysteresis loops are shown for a polycrystalline $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ film deposited onto an alumina substrate.

FIG. 4. Normalized resistances as measured at 293 K for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films made with and without barium ferrite laminations, 2:1 thickness ratio, are shown.

this temperature range. Low field magnetoresistance at room temperature, 20 °C, exhibited an enhanced $(1/R)(\Delta R/\Delta H)$ of $-2.2\%/k\text{Oe}$ for $H < 0.25/k\text{Oe}$, and an overall $(1/R) \times (\Delta R/\Delta H) = -0.24\%/k\text{Oe}$ up to 20 kOe. The low field magnetoresistance was least for the R -plane sapphire sample. Room temperature hysteresis loops for a $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ film made onto an alumina substrate are shown in Fig. 3. The in plane coercivity was ≈ 40 Oe. The room temperature $4\pi M_s$ was indicated to be 3.9 kG by the joining of the perpendicular loop to the in-plane loop.

It has been possible to eliminate the low magnetic field peaked magnetoresistance by restricting the size of the $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ grains and by restricting intergrain coupling. This was accomplished by making thin $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ film layers alternated with intervening layers of barium ferrite. Barium ferrite was chosen since it exhibits a very high resistivity compared to the $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films, and because it offers compatible film processing conditions. Figure 4 shows the room temperature normalized magnetoresistance response for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films made with and without barium ferrite laminations in a 2:1 thickness ratio. The effective resistivity of the laminated film was approximately twice the resistivity for low temperature processed polycrystalline $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ samples.³ These films were made under the same conditions onto polycrystalline alumina substrates. The laminated film had a total thickness of $1.4 \mu\text{m}$ and from average deposition per pulse calculations, consisted of 60 layers of 16-nm-thick $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ alternated with 59 layers of 8-nm-thick barium ferrite such that the first and last layers were $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$. The thickness of the layers was determined by SEM measurements of average thickness per laser pulse for separate films of $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ and barium ferrite made under the same conditions. The layered film samples were made without shadowing by sequentially switching between targets with a motorized carousel. The substrate temperature in each case was 750 °C in 120 mTorr O_2 followed by 45 min at 750 °C in 200 Torr O_2 . The intergrain coupling was sufficient to maintain electrical conduction, but it has not been possible to directly observe distinct

layers under SEM examination. The average $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ grain size is thus set equal to the average indicated thickness of 16 nm. The film made with barium ferrite laminations exhibited a linear magnetoresistance of $-0.43\%/k\text{Oe}$ from 0 to ± 5 kOe, while the $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ film exhibited the usual low field enhanced magnetoresistance. The barium ferrite layers for the deposition conditions used did not exhibit appreciable magnetic properties. Room temperature hysteresis loops for the layered film were similar to Fig. 3 in shape and exhibited a similar coercivity as for the $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ film only. The perpendicular to the film plane loop joined the in-plane loop at 2.0 kOe indicating an effective $4\pi M_s$ for the composite structure of 2.0 kG. The barium ferrite layers as deposited are thus mainly acting as nonmagnetic resistive layers.

IV. CONCLUSIONS

It has been shown that $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ polycrystalline films, in which the grain size and intergrain coupling have been restricted to an average size of 16 nm by layering with resistive barium ferrite, exhibit the usual maximum in resistivity characteristic of polycrystalline $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films. A principal difference was that only a single linear magnetoresistive response was exhibited from 0 to ± 5 kOe. This response was measured at 293 K. This temperature was 83 K above the temperature of the resistance maximum for polycrystalline $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films deposited onto alumina substrates. Reference 3 attributes the low field enhanced magnetoresistance to spin-polarized tunneling between grains in polycrystalline samples. Tunneling is expected to contribute an increased resistivity with increasing temperature⁵ that is not observed for these samples and is not expected to be dominant at room temperature. Between grain spin dependent transport is expected to be restricted in the laminated samples. That the low field response is suppressed is thus consistent with the cause of the low field magnetoresistance as depicted in Ref. 5, spin-dependent scattering of polarized electrons at grain boundaries.

Institute of Physics, Chinese Academy of Science, Beijing 100080, People's Republic of China

Colossal magnetoresistance (CMR), Mössbauer spectra, and phase compositions of the iron-doped manganites, $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ ($x=0.3$ and 0.5), have been studied. A small amount of iron doping modifies the CMR and other magnetic properties of the manganites. $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ exhibits CMR; the magnetoresistance coefficient with $H=20$ kOe and $T=225$ K is about 80%. $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ consists of two phases, $(\text{LaSn}^{2+})\text{MnO}_3$, or ABO_3 , and $(\text{LaSn}^{4+})_2\text{Mn}_2\text{O}_7$, or $\text{A}_2\text{B}_2\text{O}_7$. The ABO_3 phase has a transition from paramagnetism to ferromagnetism at $T=225$ K. The CMR has its origin in the ABO_3 phase. © 1998 American Institute of Physics. [S0021-8979(98)27011-3]

I. INTRODUCTION

The colossal magnetoresistance (CMR) in the manganites has attracted much attention. These manganites can be classified into two categories. One is the perovskite-type compound (ABO_3) with a chemical formula $(\text{R}_{1-x}^{3+}\text{D}^{2+}) \times (\text{Mn}_{1-x}^{3+}\text{Mn}_x^{4+})\text{O}_3$ ($\text{R}=\text{rare-earth}$ and $\text{D}=\text{Ca, Sr, Ba, Pb, and Cd, all divalent}$).¹ The other is the pyrochlore-type compound ($\text{A}_2\text{B}_2\text{O}_7$) with the formula $\text{Ti}_2^{3+}\text{Mn}_2^{4+}\text{O}_7$.^{2,3}

Recently, it has been discovered that $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$ exhibits CMR near room temperature (250 K).⁴ Its magnetoresistivity coefficient (classical) is as high as 74% in $H=70$ kOe. Further investigation shows that the iron doping modifies the CMR and other magnetic properties of the manganites. In this article, studies of CMR, Mössbauer spectrum, x-ray diffraction, and ac susceptibility for the iron-doped manganites $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ ($x=0.3$ and 0.5) are reported.

II. EXPERIMENT

Samples of $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ ($x=0.3$ and 0.5) as well as $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$ were synthesized using conventional ceramic techniques. A mixture of the oxides (La_2O_3 , SnO_2 , MnO_2 , and $^{57}\text{Fe}_2\text{O}_3$) of stoichiometric composition was shaped by pressure and presintered at 800 °C for 10 h. Then the samples were sintered at 1200 °C for 20 h in air.

X-ray diffraction (XRD) was performed with a Philips diffractometer using $\text{Cu } K\alpha$ radiation. The ac susceptibilities were measured at 2.4 kHz in a driving field of 30 mOe rms from 4.2 to 300 K. The magnetoresistances were examined at 4.2–300 K with zero field and a 20 kOe applied field using the standard four-probe method. Mössbauer spectra were taken between 4.2 K and room temperature with a conventional constant-acceleration spectrometer. The γ -ray source was ^{57}Co in a Rh matrix. Calibration was made using an α -Fe spectrum.

III. RESULTS AND DISCUSSION

A. Magnetoresistance

The iron-doped sample, $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ exhibits a colossal magnetoresistance. The resistances of this compound in zero and in an applied magnetic field of 20 kOe are shown as a function of temperature in Fig. 1(a). A small amount of iron doping modifies the magnetoresistance effect for $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$. Figure 1(b) shows the temperature dependences of the magnetoresistance coefficient, $\text{MR} = -\Delta\rho/\rho(0,T) \times 100\%$, in $H=20$ kOe for $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$ and the iron-doped sample. The maximum MR is as high as 80% for $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$, but only 40% for $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$. In addition, our previous work⁴ has shown that the resistivity, with increasing mag-

FIG. 1. (a) Resistance-temperature curves in zero and a 20 kOe applied magnetic field for $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$; (b) the magnetoresistance coefficient-temperature curve (circles) and also that for $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$ (squares).

FIG. 2. X-ray diffraction patterns for (a) $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ and (b) $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$. The black and white triangles represent the ABO_3 and $\text{A}_2\text{B}_2\text{O}_7$ phases, respectively.

netic fields, decreases more rapidly for $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ than for $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$; however, in the high field of 70 kOe, the MR is almost the same for both. Thus, the iron-doped sample has a larger MR in the lower fields. However, the temperature corresponding to the maximum MR is shifted toward a lower temperature, from 250 K for $\text{La}_{0.7}\text{Sn}_{0.3}\text{MnO}_{3+\delta}$ to 225 K for the Fe-doped sample.

B. Phase analyses

The x-ray diffraction patterns for $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ with $x=0.3$ and 0.5 are shown in Figs. 2(a) and 2(b), respectively. For $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ the XRD lines can be divided into two sets, denoted by the open and closed triangles in Fig. 2(a). The positions and relative intensities indicated by the closed triangles agree well with those for $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$. Therefore, this phase is identified as ABO_3 . On the other hand, the positions and relative intensities of the remaining lines are almost the same to those for $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$.

For $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$, the positions and relative intensities of the XRD lines are similar to those for $\text{La}_2\text{Sn}_2\text{O}_7$ and $\text{Ti}_2\text{Mn}_2\text{O}_7$. Hence, $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ appears to be single phase $\text{A}_2\text{B}_2\text{O}_7$ and $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ is a mixture of the two phases, ABO_3 and $\text{A}_2\text{B}_2\text{O}_7$.

C. Susceptibility

The ac susceptibilities for $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ with $x=0.3$ and 0.5 are shown in Fig. 3. For the sample with $x=0.5$, a transition from paramagnetism to ferromagnetism is not observed between room temperature and 4.2 K. Only small peaks appear at 50 and 65 K; this may imply a spin-glass transition as described by Blasco *et al.*⁵ or an antiferromagnetic transition. Their origin is as yet unsolved.

FIG. 3. Susceptibility-temperature curves for $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ and for $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$.

$\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ has two magnetic transitions. One is a transition from paramagnetism to ferromagnetism. Based on the maximum slope in dM/dH , the Curie temperature is 225 K. The other transition, indicated by the arrows in the figure, occurs at 50–65 K, the same as the transition temperature for the sample with $x=0.5$. Thus, it is concluded that the transitions observed at 225 K and at low temperature are associated with the ABO_3 and $\text{A}_2\text{B}_2\text{O}_7$ phases, respectively.

D. Mössbauer spectra

The Mössbauer spectra of $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ with $x=0.3$ and 0.5 from 300 to 4.2 K together with computer-fitted subspectra are shown in Fig. 4. The fitted Mössbauer parameters at $T=4.2$ K are listed in Table I. The isomer shifts are about 0.34–0.37 mm/s at room temperature and about 0.50 mm/s at 4.2 K for both the ABO_3 and $\text{A}_2\text{B}_2\text{O}_7$ phases. This implies that all Fe ions have ferric valency (Fe^{3+}).

The Mössbauer spectra of the sample with $x=0.5$ ($\text{A}_2\text{B}_2\text{O}_7$) are a paramagnetic doublet from room temperature to 65 K. The doublet starts to disappear and become a sextet between 65 and 50 K. The Mössbauer spectrum of the sample with $x=0.3$ has two paramagnetic doublets at room temperature. The inner doublet is associated with the ABO_3 phase and the outer doublet with the $\text{A}_2\text{B}_2\text{O}_7$ phase. The inner doublet starts to become a sextet below 230 K. However, the outer doublet remains until $T=65$ K. Only below 65 K does the outer doublet disappear; the spectra thus consist of two sextets, consistent with the previous results.⁶

The Mössbauer spectrum of the sample with $x=0.3$ with $T=4.2$ K and an applied longitudinal field of 50 kOe is shown in Fig. 4(e). The hyperfine field, $H_{\text{hf}}(H_a)$, in the presence of the applied magnetic field, H_a , is given by

$$H_{\text{hf}}(H_a) = [H_{\text{hf}}(0)^2 + H_a^2 + 2H_{\text{hf}}(0)H_a \cos \theta]^{1/2}, \quad (1)$$

where $H_{\text{hf}}(0)$ is the hyperfine field in zero applied field and θ is the angle between $H_{\text{hf}}(0)$ and H_a . The angle θ can also be obtained from the ratio of the 2nd plus 5th to the 3rd plus 4th line areas by

FIG. 4. Mössbauer spectra of (a) $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ at $T=4.2$ K, and of $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ at (b) $T=300$ K, (c) $T=77$ K, (d) $T=4.2$ K, in zero field, and (e) at $T=4.2$ K in a longitudinal applied field of 50 kOe.

$$\theta = \cos^{-1} \sqrt{\frac{4 - A_{2,5}/A_{3,4}}{4 + A_{2,5}/A_{3,4}}} \quad (2)$$

For the ABO_3 phase, $H_{\text{hf}}(H_a)$ is just equal to a sum of $H_{\text{hf}}(0)$ and H_a . Hence, $\theta=0$ obtained from Eq. (1) is consistent with the disappearance of the 2nd and 5th lines. These results show that all Fe moments are collinear but antiparallel with the applied field. Further, since ABO_3 is ferromagnetic, the Fe ions are antiparallel to the Mn ions, which have a ferromagnetic structure. The antiferromagnetic Fe–O–Mn superexchange interaction can weaken the double exchange interaction between Mn^{3+} and Mn^{4+} ions, as described by Leung *et al.*⁷ As a result, the Curie temperature is reduced for the Fe-doped sample.

TABLE I. Mössbauer parameters of $\text{La}_{1-x}\text{Sn}_x\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ ($x=0.3$ and 0.5) in zero and a 50 kOe applied field, H_a , at $T=4.2$ K. Here, δ is the isomer shift with respect to $\alpha\text{-Fe}$, ϵ is the quadrupole splitting, H_{hf} is the hyperfine field, and b is the ratio of the 2nd plus 5th to the 3rd plus 4th.

Sample	Phase	δ (mm/s)	$H_a=0$ kOe ϵ (mm/s)	H_{hf} (kOe)	b
$x=0.5$	$\text{A}_2\text{B}_2\text{O}_7$	0.50(3)	-0.46(3)	474(3)	2.0
$x=0.3$	$\text{A}_2\text{B}_2\text{O}_7$	0.51	-0.64	474	2.0
	ABO_3	0.50	0.03	525	2.0
$x=0.3$	$\text{A}_2\text{B}_2\text{O}_7$	0.47(3)	$H_a=50$ kOe -0.41(3)	514(3)	1.30
	ABO_3	0.56	0.04	576	0.0

For the $\text{A}_2\text{B}_2\text{O}_7$ phase, the Mössbauer subspectrum is still a sextet in an applied field of 50 kOe; therefore the antiferromagnetic coupling between the Fe moments is excluded. The nonzero 2nd and 5th lines imply that the Fe moments are noncollinear. The average angle $\langle\theta\rangle$ is estimated to be about 36° from Eq. (1) and about 44° from Eq. (2). Therefore, the Fe moments in the $\text{A}_2\text{B}_2\text{O}_7$ phase may be either canted with ferromagnetic coupling or be in a spin-glass state.

IV. CONCLUSIONS

A small amount of iron doping modifies the CMR and other magnetic properties of the manganites. $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ exhibits CMR; the magnetoresistance coefficient in $H=20$ kOe and at $T=225$ K is about 80%. $\text{La}_{0.5}\text{Sn}_{0.5}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ is a single phase with the $\text{A}_2\text{B}_2\text{O}_7$ structure and $\text{La}_{0.7}\text{Sn}_{0.3}\text{Mn}_{0.985}\text{Fe}_{0.015}\text{O}_{3+\delta}$ is a mixture of the ABO_3 and $\text{A}_2\text{B}_2\text{O}_7$ phases. The ABO_3 phase is associated with a transition from paramagnetism to ferromagnetism at $T=225$ K and the $\text{A}_2\text{B}_2\text{O}_7$ phase with another transition between 50 and 60 K. Hence, the CMR has its origin in the ABO_3 phase.

We have performed electron spin resonance (ESR) and dc susceptibility, $\chi_{dc}(T)$, measurements in $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ perovskite up to 1000 K. This is adequately described in the paramagnetic regime in the constant coupling approximation assuming an effective Heisenberg-like pair interaction. The ESR linewidth is given by $\Delta H_{pp}(T) = \Delta H_{pp}(\infty)[C/T\chi(T)]$. The ESR intensity follows the T dependence of $\chi_{dc}(T)$. We conclude that the relaxation mechanism is essentially the same for the whole studied paramagnetic range. The observed behavior reflects the progressive importance of magnetic clustering on approaching T_c . We have found similar T dependence for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ and $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$ perovskites, and also for the pyrochlore $\text{In}_2\text{Mn}_2\text{O}_7$. © 1998 American Institute of Physics. [S0021-8979(98)27111-8]

The discovery of “colossal” magnetoresistance (CMR) in manganese oxides has renewed the interest in this kind of material. Perovskites $\text{A}_{1-x}\text{A}'_x\text{MnO}_3$ ($\text{A}=\text{La}, \dots; \text{A}'=\text{Ca}, \text{Sr}, \dots$) with $x \approx 0.3$ exhibit CMR effects near the paramagnetic (PM) to ferromagnetic (FM) transition temperature, T_c . These oxides show electron spin resonance (ESR) lines in the PM phase with large variations as a function of T and a large increase in intensity near T_c reflecting the dependence of the static susceptibility.¹⁻³ However the agreement between the measured intensities and a Curie-Weiss (CW) law was not satisfactory above 500 K. Simultaneously a change in the slope of the linewidth, ΔH_{pp} vs T was observed. It was suggested¹ that these effects may be due to the formation of $\text{Mn}^{3+}-\text{Mn}^{4+}$ spin clusters when T_c is approached from above. On the other hand, a possible mechanism related to a crossover from a bottlenecked regime where Mn^{3+} and Mn^{4+} are strongly coupled to an isothermal one where a decrease of the ESR intensity may be expected has been discussed.³ Studies in an extended temperature range were required^{2,3} in order to correlate these observations with theoretical models for CMR involving double exchange and electron-phonon interactions. We have performed ESR and magnetization measurements up to 1000 K, including the pyrochlore $\text{In}_2\text{Mn}_2\text{O}_7$ to compare the properties of ferromagnetic Mn oxides with different crystalline structures.

Ceramic samples of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ were prepared from the oxides by standard methods. Structure and phase purity were checked by powder x-ray diffraction. A single crystal of $\text{La}_{0.67}\text{Pb}_{0.33}\text{MnO}_3$ was also measured. Pyrochlore $\text{In}_2\text{Mn}_2\text{O}_7$ was prepared through solid state reactions under a

pressure of ≈ 35 kbar as described in Ref. 4. The dc magnetic susceptibility, $\chi_{dc}(T)$, was measured using a Faraday balance and a SQUID magnetometer. ESR measurements were performed at $\omega=1.2, 9.4$, and 34 GHz with an ESP-300 Bruker Spectrometer from 100 to 300 K. For 9.4 GHz the measurements were extended up to 1000 K.

At high temperatures $\chi_{dc}(T)$ follows a CW dependence, $\chi_{dc}(T) = C/(T - \Theta)$. For temperatures below $\approx 1.5 \Theta$, the curve for the inverse susceptibility vs T shows a positive curvature (see Fig. 1) and $\chi_{dc}(T)$ diverges at $T_c < \Theta$. Both temperatures are given in Table I.

The double exchange interaction is used to describe the FM interaction between Mn ions in CMR perovskites. A simplified model for this interaction⁵ indicates that the hop-

FIG. 1. Inverse susceptibility vs T for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$. Small circles correspond to $\chi_{dc}(T)$, large circles to $\chi_{ESR}(T)$ from $(\Delta H_{pp})^2/h_{pp}$ and triangles to $\chi_{ESR}(T)$ from numerical integration.

TABLE I. Values for the Curie constant, Curie-Weiss and critical temperatures, and exchange constant obtained from susceptibility measurements.

Compound	C emu K mol	Θ (K)	T_c (K)	T_c/Θ	J/k_B
$\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$	2.8(1)	368	260	0.69	49
$\text{In}_2\text{Mn}_2\text{O}_7$	2.4(1)	145	130	0.89	10

ping of electrons between Mn^{4+} ions couples them forming high spin magnetic clusters. The effective FM coupling for Mn ions that results from this model may be described by an isotropic Heisenberg like interaction between Mn^{3+} ($3d^4$) and Mn^{4+} ($3d^3$) pairs.

$$\mathcal{H} = -2J \sum_{\langle i,j \rangle} S_1^i \cdot S_2^j, \quad (1)$$

where S_1 and S_2 identify the spin of Mn^{4+} and Mn^{3+} species, respectively, with $S_1 = 3/2$ and $S_2 = 2$.

In the Weiss mean field approximation (WMFA), the high-temperature behavior associated with this Hamiltonian, is given by a CW law with $C = N_A g^2 \mu_B^2 (f_1 + f_2) / 3k_B$ and $k_B \Theta / J = 4z f_1 f_2 / 3(f_1 + f_2)$, where z is the number of nearest neighbors and $f_1 = x S_1(S_1 + 1)$, $f_2 = (1-x) S_2(S_2 + 1)$. For $x = 0.33$, the calculated value is $C = 2.64$ emu K mol, which is compared with the experimental results of Table I. We have derived values for J from the measured Θ , also listed in Table I.

The main assumption of the WMFA model is the statistical independence of the spins, neglecting the short range order, which produces the curvature in $\chi_{dc}^{-1}(T)$. Small clusters models,⁶ such as the constant coupling approximation (CCA) takes into account the correlation between neighboring spins. The magnetic system is considered as an ensemble of spin pairs interacting through an effective Hamiltonian,

$$\mathcal{H} = -2JS_1 \cdot S_2 + g\mu_B(S_1 + S_2) \cdot [H + H_e], \quad (2)$$

where H_e is an effective field acting on the pair, determined by consistency requirements.⁶ A consequence of treating in more detail the formation of magnetic clusters (pairs in the CCA) is the appearance of short range order above T_c with a simultaneous reduction of $H_e(T)$, as compared to the values derived in the WMFA. Thus, the long range order is achieved at a temperature $T_c < \Theta$ and the calculated susceptibility adequately describes the positive curvature shown in Fig. 1. The experimental values for the ratio T_c/Θ (see Table I) are consistent with the values calculated⁶ in the CCA for either $S = 3/2$ or 2 ($T_c/\Theta = 0.77$ and 0.79, respectively).

In the case of pyrochlore $\text{In}_2\text{Mn}_2\text{O}_7$, the mechanisms for electrical conduction and magnetism are related⁷ to the intermediate valence arising from a hybridization of Mn $3d$ electrons with the conduction bands of In. In this case the magnetic interactions occurs between Mn^{4+} ($S = 3/2$) ions. Our susceptibility data, in coincidence with previous reports,⁸ shows the same positive curvature present in the perovskites.

The paramagnetic ESR spectrum of powdered samples consists of a single lorentzian line with a g value of 1.992(3), which is constant and independent of the microwave frequency at high temperatures. Since the ESR signals are in-

tense near T_c , the measured linewidth, ΔH_{pp} , is dependent on sample mass due to "overloading" of the cavity.⁹ In order to avoid these effects we repeated the experiments at each temperature with different amounts of material extrapolating to zero mass.

As a function of T , the ESR linewidth showed a behavior similar to that described in previous reports^{1,3}: When T approaches T_c from above, $\Delta H_{pp}(T)$ decreases and goes through a minimum at $T_{\min} > T_c$. The value of T_{\min} and the rate of increase of the linewidth below this temperature are dependent on the microwave frequency. Variations of the g factor were also observed for $T_c < T < T_{\min}$. Above T_{\min} the g factor is constant and $\Delta H_{pp}(T)$ independent of frequency.

The intensity of the ESR spectrum, $I(T)$, is an important parameter to identify the nature of the resonant species^{1-3,10} through the temperature dependence of χ_{ESR} , corresponding to the resonant species. There are several experimental difficulties in the determination of $I(T)$ because the linewidth increases by ≈ 10 from T_{\min} to high temperatures and the peak-to-peak amplitude of the measured derivative signal, h_{pp} , decreases up to three orders of magnitude in the same T range. This is a probable cause for the disagreement between recently reported results.^{1-3,10} Since the differences led the authors to different interpretations we have made a careful determination of $I(T)$ for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$, up to 1000 K, that may shed some light on this controversial subject. $I(T)$ was determined by numerical double integration of the spectra and also approximating the area by $\Delta H_{pp}^2 h_{pp}$. In order to obtain $\chi_{\text{ESR}}(T)$, shown in Fig. 1, we have renormalized the measured $I(T)$ using values of Q_L determined at each temperature. We found that the temperature dependence is the same for both χ_{ESR} and χ_{dc} . Between T_c and T_{\min} significant line-broadening and g shifts, both dependent on microwave frequency, were observed. Since these effects, related¹⁰ to the proximity of T_c , may confuse the analysis of the results in the paramagnetic regime we have not included this temperature region in the analysis.

The temperature dependence of $\Delta H_{pp}(T)$ above T_{\min} was originally found¹ to be almost linear with T for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ up to 700 K and similar results were recently reported¹⁰ up to 600 K for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$. A small tendency to saturation was found later^{2,3} above $T \approx 600$ K. Up to this temperature, our results for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$, $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$, and $\text{La}_{0.67}\text{Pb}_{0.33}\text{MnO}_3$ present the same quasilinear behavior. In the case of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$, we have extended the measurements up to ≈ 1000 K and found significant deviations from linearity at high temperatures, as shown in Fig. 2(a). For $\text{In}_2\text{Mn}_2\text{O}_7$, see Fig. 2(b), a similar T dependence was observed.

In treating the T dependence of ΔH_{pp} of magnetic compounds in the PM region, Dormann and Jaccarino¹¹ argued, following Huber's¹² approach, that the main variation is given by the expression

$$\Delta H_{pp}(T) = [\chi_s(T)/\chi_{\text{ESR}}(T)] \Delta H_{pp}(\infty), \quad (3)$$

where $\chi_s(T) = C/T$ is the single ion susceptibility and $\chi_{\text{ESR}}(T)$ corresponds to the paramagnetic behavior of the coupled system. The continuous line in Fig. 2, drawn with $\chi_{dc}(T)$ data, shows an excellent agreement with the experi-

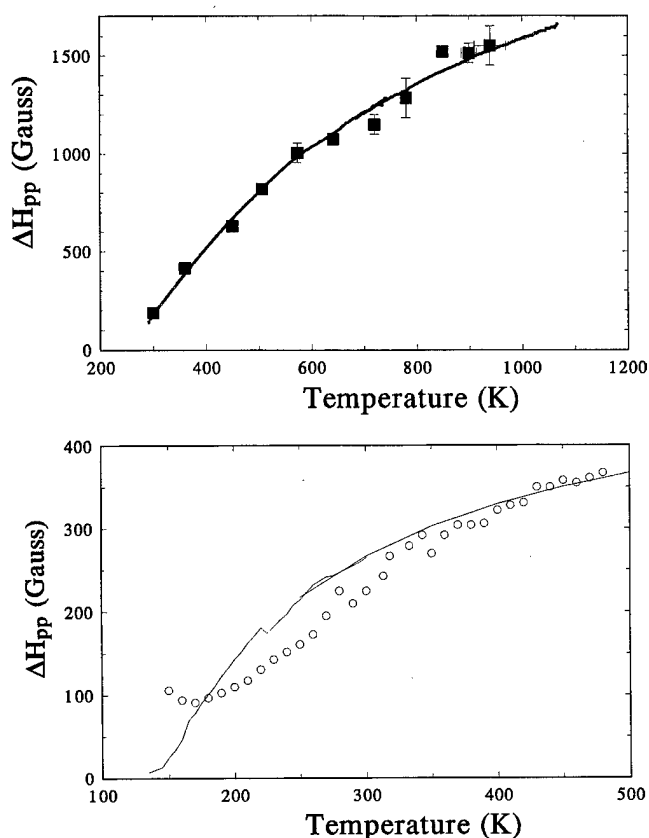

FIG. 2. ΔH_{pp} vs T taken at X band for (a) $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and (b) $\text{In}_2\text{Mn}_2\text{O}_7$. Solid lines correspond to Eq. (3).

mental $\Delta H_{pp}(T)$, including not only the quasilinear behavior near T_c , but also the saturation at higher temperatures. For $\text{In}_2\text{Mn}_2\text{O}_7$, the T dependence is also well described, although with small systematic departures near T_c , that may be related to spin-glass-like behavior.⁸

The limiting values $\Delta H_{pp}(\infty) = 2500$ and 500 G, determined for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{In}_2\text{Mn}_2\text{O}_7$, respectively, corresponds to spin-spin interactions.¹² If the only anisotropic contributions were of dipolar origin, exchange narrowed lines would be expected. Using the J values of Table

I calculated values for $\Delta H_{pp}(\infty)$ are of the correct magnitude for $\text{In}_2\text{Mn}_2\text{O}_7$, but about an order of magnitude smaller for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$. Therefore, other anisotropic interactions must be considered in order to explain our results.¹³

In conclusion, we have analyzed in detail the temperature dependence of the dc susceptibility and ESR line parameters in the PM regime of FM manganites. We found that: (a) The static magnetic susceptibility $\chi_{dc}(T)$ is well described in a mean field approximation of the small cluster type, although the ratio T_c/Θ calculated in the CCA is slightly different than that calculated for either $S = 3/2$ or $S = 2$. (b) The temperature dependence of the ESR of the system, independently of the exact nature of the resonant species, may be described by a common curve, whose temperature scale is determined by T_c and the infinite temperature linewidth kept as an adjustable parameter related to spin-spin interactions.

We report on a comparative study of three manganites: $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$, $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$, and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$, which all exhibit the same $\text{Mn}^{3+}/\text{Mn}^{4+} = 1:1$ concentration but show a very distinct magnetic behavior. The $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ sample is a ferromagnet (FM) below $T_C = 265$ K and becomes the A-type antiferromagnet at $T_N = 140$ K. In $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ the charge order develops at $T_{CO} = 245$ K and the CE-type antiferromagnetism occurs below $T_N = 175$ K. The $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ sample exhibits the FM transition at $T_C = 225$ K and the CE type antiferromagnetism and charge ordering occur simultaneously at $T_N = T_{CO} = 160$ K (185 K) upon cooling (heating), respectively. The study is complemented by the data on two systems of 30% Mn^{4+} , the ferromagnetic metal $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$, and insulator $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$, both with similar Curie temperature $T_C \sim 140$ K. The electrical resistivity, thermoelectric power, thermal conductivity, and volume thermal expansion data are analyzed with respect to observed magnetic transitions and reveal the significantly distinct ground state of the A-type and CE-type antiferromagnets. We suppose that phonons and charge carriers are coupled via the Jahn–Teller effect and the CMR effect observed in manganites originates thus from a mutual interplay of a strong electron–phonon interaction and spin order. © 1998 American Institute of Physics.

[S0021-8979(98)32011-3]

Ferromagnetic perovskites $\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$ with a high concentration of formally tetravalent manganese have become a subject of numerous studies. The competing ferromagnetic and antiferromagnetic interactions for the samples with nominal $\text{Mn}^{3+}/\text{Mn}^{4+} \sim 1:1$ concentration have been shown to lead to fascinating transport anomalies below room temperature. The magnetic and transport properties of these perovskites are in some sense predetermined by the crystal structure, which is principally controlled by the interlayer mismatch expressed as Goldschmidt's tolerance factor. A number of important additional factors, both cooperative [Jahn–Teller (J-T) distortion, orbital, and charge ordering] and local (ion size mismatch) critically influence, however, the thermodynamic stability of the competing phases. Besides, the role of dynamic J-T modes coupled with carriers and the existence of magnetic polarons was recently underlined.^{1,2} One of the feasible methods used to probe complexly these interactions is the investigation of thermal properties in comparison to magnetic, structural, and electrical data. In this article we report on the thermal conductivity, thermal expansion, thermoelectric power, and electrical resistivity measurements on praseodymium based samples with 30% and 50% Mn^{4+} concentration.

Ceramic samples were prepared using a solid state reaction from appropriate amounts of respective oxides and carbonates as described elsewhere.^{3,4} Structural characterization of the 50% samples has been done by the neutron diffraction. The thermal expansion was calculated using the refined lattice parameters, whereas for the 30% samples, this quantity was measured using the strain gauge method. All the thermal conductivity and transport data were measured using the

steady state four point technique from 12 to 300 K. The results of the thermal conductivity and electrical resistivity were corrected for the sample porosity.

The neutron diffraction on the 50% samples showed that $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ is ferromagnet below $T_C = 265$ K and upon further cooling it exhibits an antiferromagnetic transition at $T_N = 140$ K. The observed A (planar) type of the antiferromagnetism is not compatible with any $\text{Mn}^{3+}/\text{Mn}^{4+}$ order; the lattice distortion below T_N shows, however, that the partially occupied manganese $3d_{\gamma}$ orbitals are oriented at the transition into the MnO_2 planes. A different situation is encountered in $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$. The $\text{Mn}^{3+}/\text{Mn}^{4+}$ (1:1) order occurs at $T_{CO} = 245$ K and an antiferromagnetism of a complex kind (CE type) develops below $T_N = 175$ K. The third compound under investigation $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ exhibits the ferromagnetic transition at $T_C = 225$ K and, contrary to pure Sr or pure Ca doped samples, the CE type antiferromagnetism and charge ordering occur simultaneously at $T_N = T_{CO} = 160$ K (185 K) upon cooling (heating), respectively.

The transport properties of the studied samples below the room temperature are shown in Figs. 1 and 2 where the temperature dependences of electrical resistivity and thermoelectric power are displayed. In $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ the ferromagnetic transition at 265 K is accompanied by a small decrease of electrical resistivity, which is followed by an increase at the antiferromagnetic transition at 140 K. Even at the lowest temperatures the conductivity remains high which suggests that the $3d_{\gamma}$ electrons in the MnO_2 planes are delocalized. Both in $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$, the conduction is strongly activated with a pronounced anomaly at the charge ordering temperatures while the ferromagnetic

FIG. 1. Temperature dependence of the electrical resistivity for $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (\circ), $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (\square), and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ (\triangle). In the inset the data for $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ (\diamond) and $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ ($+$) are displayed. The arrows denote the ferromagnetic (T_C), antiferromagnetic (T_N), and charge order (T_{CO}) transition temperatures.

transition in $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ at 225 K is nearly invisible. For a comparison, the coincidence of the ferromagnetic and I - M transition in the CMR compound $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ with $R(0\text{ T})/R(5\text{ T})=20$ at T_C is exemplified in the inset while no metallic transition occurs in another 30% sample $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ where dissimilar size of the substituent leads to a localization of carriers.³

The temperature independent and negative thermoelectric power in the paramagnetic state of the 50% samples is in general agreement with previously published results and can be understood if polaronic carriers strongly interact with the spin background. The thermopower is then dominated by the configurational entropy term where both the spin and orbital degeneracy should be considered.⁵ A detailed analysis is, however, out of the scope of this work. The ferromagnetic transition, if present, is always accompanied by a decrease of the absolute value of thermopower. The barely metallic states could be thus indicated also in $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ and

FIG. 2. temperature dependence of the thermoelectric power for $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (\circ), $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (\square), and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ (\triangle). In the inset the data for $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ (\diamond) and $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ ($+$) are displayed.

FIG. 3. Temperature dependence of the thermal conductivity for $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (\circ), $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (\square), and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ (\triangle). In the inset the data for $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ (\diamond) and $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ ($+$) are displayed.

$\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ samples despite their increasing resistivity below T_C . The charge ordering transition in $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ is characterized by a divergence of the thermopower to large negative values while the onset of antiferromagnetic order in $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ is evidenced only by a small drop down to $\sim 25\text{ }\mu\text{V K}^{-1}$, followed by a thermodynamical return to zero.

In order to visualize the interrelation of the transport and lattice effects, the thermal conductivity and the volume thermal expansion data are displayed in Figs. 3 and 4. For samples $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$, the temperature dependence of lattice parameters is included in the lower panel of Fig. 4. It should be noted that an analysis of observed electrical and thermal conductivities on the basis of the Wiedemann-Franz law, which enables one to estimate the upper limit of the electronic part of the thermal conductivity using the Lorenz number, excludes any appreciable electronic contribution to the heat transport even in the metallic samples. So the thermal conductivity is confined essentially to phonons and their scattering processes. In agreement with previously published data on the $\text{Mn}^{3+}/\text{Mn}^{4+}$ perovskites^{6,7} the measured values of thermal conductivity are extremely low and comparable with glassy materials. As a possible explanation one can consider large static disorder due to localized Mn^{4+} defects (in Mn^{3+} concentrated systems with strong J-T effects), the electron and/or spin density fluctuations observed as static objects (coherent length of tens Å) at low doping and present presumably as itinerant magnetic polarons at higher doping of carriers and, finally, the presence of anomalous acoustic phonons. These anomalous phonons may arise due to coupling with soft optical modes which have locally character of octahedra tiltings or vibrations of the J-T type. In the paramagnetic region of perovskites with 30%–50% Mn^{4+} the low thermal conductivity (actual mean free path of phonons $\sim 10\text{ Å}$) can be associated with magnetic polarons and/or vibronic interactions of Mn^{3+} ions (the dynamic Jahn-Teller modes). The latter possibility seems to be more relevant since the thermal conduction is essentially low even in the ferromagnetic state where magnetic polarons should vanish.

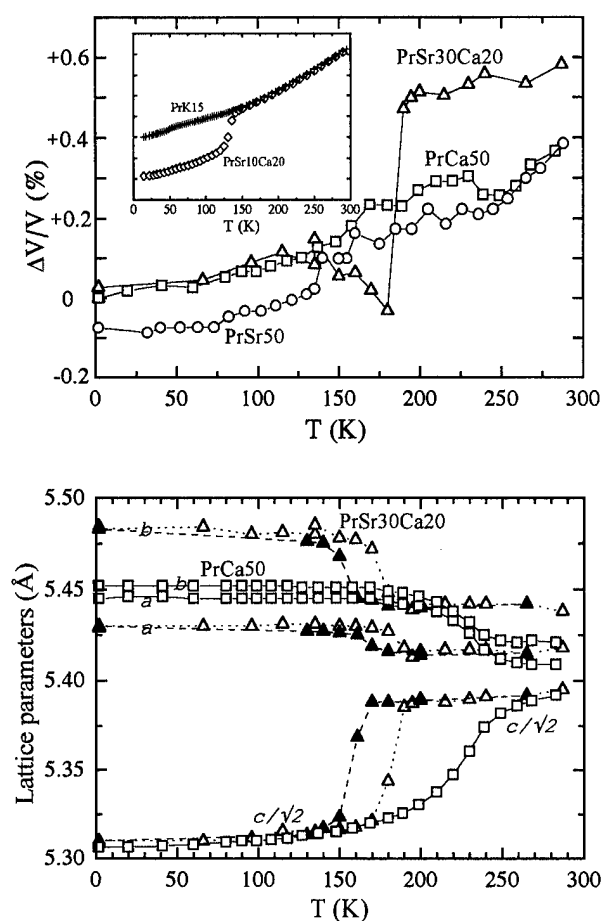

FIG. 4. Upper panel: the volume thermal expansion for $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (\circ), $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (\square), and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ (\triangle), $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ (\diamond), and $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ ($+$). Lower panel: the temperature dependence of the lattice parameters for $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (\square) and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ (\triangle). Open symbols represent the temperature increase, full symbols the temperature decrease. The data are normalized with respect to two ground states (metallic and insulating) which differ in volume of $\sim 0.15\%$. (See Ref. 8).

The insets of Figs. 3 and 4 show the thermal behavior for 30% Mn^{3+} . In the case of the $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ sample, the simultaneous magnetic and I - M transition is accompanied by a sharp increase of the thermal conductivity below T_C , while for the insulating $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ no enhancement is observed. The sharp decrease of the unit cell volume of about $\sim 0.15\%$ in $\text{Pr}_{0.7}\text{Sr}_{0.1}\text{Ca}_{0.2}\text{MnO}_3$ and the absence of this anomaly in $\text{Pr}_{0.85}\text{K}_{0.15}\text{MnO}_3$ points out the first order character of the I - M transition and underlines the different ground state of the two samples. Moreover, these results indicate that the enhancement of thermal conductivity cannot be linked to the ferromagnetism alone and is rather due to an electronic transition which suppresses significantly the amplitude of dynamic J-T modes. This supports the previous hypothesis that the J-T modes are the principle scatterers of phonons in manganese perovskites.

Enhancement of the thermal conductivity below T_C is observed also in the 50% Mn^{4+} samples $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ and $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$. The volume anomaly is absent, however, suggesting that the transition is not of the first order. With further cooling the thermal conductivity is suppressed

at the antiferromagnetic temperature T_N and recovers its value extrapolated from the paramagnetic domain. The depression of the thermal conductivity in $\text{Pr}_{0.5}\text{Sr}_{0.3}\text{Ca}_{0.2}\text{MnO}_3$ is accompanied by a sharp and exceptionally large decrease of the unit cell volume which makes about -0.5% . This effect is related to a specific arrangement of octahedral tilts in this compound at elevated temperatures, which are suddenly reorganized with the charge ordering at $T_N = T_{CO}$. The large drop of volume is followed by a smaller and gradual increase between 185 and 150 K. This is a common effect of orbital ordering, associated with increasing size of the Mn^{3+}O_6 octahedra with the J-T distortion.

In the case of $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ the orbital ordering at $T_{CO} = 245$ K is characterized by a small increase of the unit cell volume, but the transition is not accompanied by any marked anomaly in the thermal conductivity. The thermal conductivity shows, however, a minimum at 180 K and a broad enhancement at lower temperatures. Below 100 K it surpasses significantly the thermal conductivity of the $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ sample. The minimum of thermal conductivity is likely associated with a small decrease of the unit cell volume at 170 K. The occurrence of the anomaly close to $T_N = 175$ K instead of T_{CO} could be related to the fact that the transition from the high temperature disordered state to the ordered one is diffusive—see the lower panel of Fig. 4.

In summary, we have studied the magnetic, transport, thermal, and structural properties of several praseodymium based manganites. It appears that the CE- and A-type antiferromagnetic phases exhibit quite distinct transport properties, their ground state is insulating in the former and conducting (2-dim) in the latter one; the itinerant behavior being restricted to the ferromagnetically coupled MnO_2 layers in which the $\text{Mn}^{3+}/\text{Mn}^{4+}$ ordering is in fact absent. In all systems the thermal conductivity is low. We associate this observation with phonon scattering processes which involve the dynamics of d_γ states. These active J-T modes are often partially frozen and can be then evidenced by diffraction methods as small, ordered, or disordered distortions. The thermal conductivity is enhanced only when the electronically homogeneous state (metallic or insulating) is formed. In that case the dynamic J-T modes are suppressed or a complete (static) J-T ordering develops.

The stability of the exchange biasing field, H_{eb} , has been studied for NiO/Ni₆₆Co₁₈Fe₁₆ bilayers. A forced antiparallel alignment of the ferromagnetic magnetization to H_{eb} results in a gradual decrease and even a reversal of H_{eb} . The decrease of H_{eb} increases with temperature and is independent of the external field and NiO layer thickness. This decrease can be interpreted by a thermally assisted relaxation process. A new effect of the relaxation process on H_{eb} is demonstrated by using different cooling rates. © 1998 American Institute of Physics. [S0021-8979(98)18111-2]

I. INTRODUCTION

Direct exchange coupling at the interface between a ferromagnetic (F) layer and an antiferromagnetic (AF) layer may result in exchange biasing,¹ which induces a unidirectional anisotropy of the F layer. The unidirectional anisotropy gives rise to a shift of the hysteresis loop of the F layer along the field axis, which is equal to the exchange biasing field, H_{eb} . The magnitude of H_{eb} depends on temperature and becomes zero at a temperature called the blocking temperature, T_B . It is known that directing the external field (and thereby the magnetization of the F layer) antiparallel to H_{eb} while cooling at temperatures below T_B results in a decrease of H_{eb} .^{2,3}

Recently, we have shown that an antiparallel alignment of the magnetization of the F layer to H_{eb} at a constant temperature results in a gradual decrease and even a reversal of H_{eb} .⁴ The observed behavior of H_{eb} is interpreted by a macroscopic two-level model. The two-level model can result from an AF layer consisting of AF domains with uniaxial anisotropy, which are laterally decoupled and exchange-coupled to the F layer following Fulcomer and Charap.⁵ This results in an absolute and a local energy minimum for the sublattice (staggered) magnetization direction of an AF domain, see insets of Fig. 1. After cooling the sample in an applied magnetic field from above T_B to a certain temperature below T_B , the staggered magnetization directions of the AF domains are assumed to be distributed over the two energy minima according to the Boltzmann distribution function. This situation (at $t=0$) gives rise to the observed ex-

change biasing field and is shown in the inset (a) of Fig. 1. The forced antiparallel alignment of H_{eb} and the magnetization of the F layer after $t=0$ results in an interchange of the two energy minima. Subsequently, a thermally assisted redistribution of the now nonequilibrium distribution of the staggered magnetization directions of the AF domains occurs [see inset (b) of Fig. 1] and, therefore, a relaxation of H_{eb} . Among others, the relaxation time of an AF monodomain

FIG. 1. The time dependence of H_{eb} at 425 K for Si(100)/40 nm NiO/5 nm Ni₆₆Co₁₈Fe₁₆/5 nm Ta. At $t=0$ the external field is reversed, forcing an antiparallel alignment of the magnetization of the F layer and H_{eb} (circles). After 42 h (2520 min.), the direction of the external field and thereby the magnetization of the F layer is reversed again (squares). The line after $t=2520$ min. represents the inverted data for H_{eb} after $t=0$. The insets show a schematic representation of dependence of the energy per unit area, E_s , on the angle ϕ of the staggered magnetization of an AF domain with uniaxial anisotropy, which is exchange coupled to a F layer with the magnetization directed along $\theta=0$ (a) and π (b). The circles represent the distribution over the two minima at thermal equilibrium, $t=0$ (a) and just after the reversal of the magnetization of the F layer (b).

^{b)}Present address: CVC Products, 3100 Laurelview Court (Bldg. H), Fremont, CA 94538.

increases with thickness, which is assumed to be correlated to the grain size.

Here, we report to which extent the Fulcomer-Charap model provides an at least qualitative description of the observed decrease of H_{eb} after reversing the applied field (and thereby the magnetization direction of the F layer) at $t=0$. The implications of the model for the observed $H_{eb}(t)$ are demonstrated by experiments using different cooling rates from above T_B to room temperature.

II. EXPERIMENTAL DETAILS

Samples consisting of Si(100)/40 or 60 nm NiO/5 nm $\text{Ni}_{66}\text{Co}_{18}\text{Fe}_{16}$ /5 nm Ta were grown at room temperature in an applied field of 10–15 kA/m by a multisource sputter apparatus. Pressure prior to deposition was typically 10^{-8} Torr. The metallic layers were deposited by dc-magnetron sputtering at a pressure of 5 mTorr Ar and the NiO layers were deposited by rf-magnetron sputtering from a NiO target in an Ar pressure of 1 mTorr. After deposition, the samples were annealed up to 500 K after which the samples were field-cooled down to room temperature in about 10 h in order to improve the exchange biasing.

The experiments were carried out using a variable temperature Magneto-Optical Kerr Effect (MOKE) apparatus. The sample was heated from room temperature to the desired temperature in an external field, which was applied parallel to H_{eb} . Subsequently, H_{eb} was measured as a function of time at a constant temperature and external field. Note, that H_{eb} was obtained from a hysteresis loop measurement during which the direction of the applied field (and the magnetization of the F layer) was varied. This implies that relaxation contributions to H_{eb} faster than half the hysteresis loop time of 12 s cannot be observed.

III. RESULTS AND DISCUSSION

The blocking temperature for the NiO/ $\text{Ni}_{66}\text{Co}_{18}\text{Fe}_{16}$ bilayers is 480 K, as determined from the temperature dependence of H_{eb} ,⁴ which is similar to the results obtained by others.³ Figure 1 shows H_{eb} as function of time at 425 K for Si(100)/40 nm NiO/5 nm $\text{Ni}_{66}\text{Co}_{18}\text{Fe}_{16}$ /5 nm Ta. At $t=0$ an external field is applied, which forces an antiparallel alignment of the magnetization of the F layer and H_{eb} . A gradual decrease of H_{eb} is observed resulting in zero exchange biasing within 2 h after which H_{eb} changes sign and becomes negative. After 42 h the external field and thereby the magnetization direction of the F layer is reversed, which results in an increase of H_{eb} . The increase of H_{eb} as a function of time is identical to the inverted behavior of H_{eb} observed after $t=0$. The reversibility of the time dependence of H_{eb} upon the reversal of the external applied field (and thereby the magnetization direction of the F layer) implies a magnetic origin and not some structural cause for the change in H_{eb} .

Within the Fulcomer-Charap model the relaxation of H_{eb} arises from the redistribution of the staggered magnetization directions of the AF domains due to the exchange coupling between the AF domains and the F layer. However, the magnetization directions of the AF domains may also be

FIG. 2. The time dependence of H_{eb} at 425 K for Si(100)/40 nm NiO/5 nm $\text{Ni}_{66}\text{Co}_{18}\text{Fe}_{16}$ /5 nm Ta applying different magnitudes of the external field antiparallel to H_{eb} . The magnetization of the F layer is directed parallel to H_{eb} for an external field of -6 kA/m (up triangles) and antiparallel to H_{eb} for external fields of -45 kA/m (squares) and -125 kA/m (circles). The inset shows the hysteresis loop measurement at $t=0$.

influenced by an external applied field, e.g., if an AF domain possess a small magnetic moment due to finite size effects^{6,7} and the exchange coupling energy at the AF and F interface is smaller than the Zeeman coupling energy of the AF domain.⁸ Figure 2 shows the time dependence of H_{eb} for different magnitudes of the external field applied antiparallel to H_{eb} . The figure shows that a decrease of H_{eb} is only observed if the magnetization direction of the F layer is antiparallel to H_{eb} , but is independent of the magnitude of the (small) external field.

Figure 3 shows the normalized exchange biasing fields as a function of time during an antiparallel alignment of H_{eb} and the magnetization of the F layer at different temperatures for samples consisting of a 40 to 60 nm NiO layer. The exchange biasing fields are normalized to the initial value at $t=0$. The gradual decrease of H_{eb} increases with temperature, which is discussed elsewhere.⁴ Apart from the curves at 375 K, the decrease of H_{eb} is independent of the AF-layer thickness, which is inconsistent with the assumption that the AF grains are monodomain throughout the entire AF-layer.

FIG. 3. The exchange biasing field, H_{eb} as function of time at different temperatures during a forced antiparallel alignment of the magnetization of the F layer and H_{eb} . The squares and circles represent the data of samples consisting 40 and 60 nm NiO/5 nm $\text{Ni}_{66}\text{Co}_{18}\text{Fe}_{16}$ /5 nm Ta grown on Si(100), respectively. The values of H_{eb} are normalized to the initial value $t=0$.

FIG. 4. The figure shows H_{eb} as function of time at 290 K after field cooling from 550 K down to 290 K in 2 min for Si(100)/40 nm NiO/5 nm $\text{Ni}_{66}\text{Co}_{18}\text{Fe}_{16}$ /5 nm Ta. Subsequently, the sample is heated up to 432 K in 20 min after which again the time dependence of H_{eb} is measured. During these experiments the magnetization of the F layer is directed parallel to H_{eb} . Note the break in the time axis.

thickness. In that case the relaxation rate of H_{eb} would be expected to reduce with increasing AF-layer thickness for columnar grown AF layers. Columnar growth has been observed for these NiO layers by transmission electron microscopy experiments.

Interestingly, the distribution of the AF domains over the two energy minima is not only influenced by the magnetization direction of the F layer, but also by a change in temperature. Decreasing the temperature results in a new equilibrium distribution, which will only be attained if the relaxation rate is faster than the cooling rate. This implies that the magnitude of H_{eb} is not only influenced by the direction of the magnetization of the F layer during cooling below T_B , which is already demonstrated by others,^{2,3} but also by the cooling rate. The effect of varying the cooling rate has been investigated by field cooling from above T_B to 290 K in 2 min instead of our standard 10 h. This results in a decreased H_{eb} of 9 kA/m, at $t=0$, instead of 12 kA/m. Figure 4 shows the subsequent variation of H_{eb} as a function of time for a *parallel* alignment of the magnetization of the F layer and H_{eb} after cooling in 2 min. The time dependence of H_{eb} at 290 K shows a constant value for H_{eb} indicating that the thermal energy is too small to relax the nonequilibrium distribution of the AF domains. However, after increasing the temperature to 432 K in 20 min, a relaxation of H_{eb} is observed from 2.7 kA/m to about 4.8 kA/m (see Fig. 4). Subsequent slow cooling to 290 K in about 7 h results in an increased value for H_{eb} of 13 kA/m.

IV. CONCLUSIONS

We have shown that the gradual decrease of H_{eb} during a forced antiparallel alignment of the magnetization of the F

layer to H_{eb} results from the exchange coupling at the F and AF interface and is independent of the (small) external field. The decrease of H_{eb} as a function of time increases with temperature indicating a thermally assisted relaxation process. These three observations are consistent with the model proposed by Fulcomer and Charap in which the decrease of H_{eb} is described by a thermally assisted relaxation process of AF domains, which are mutually decoupled and exchange-coupled to the F layer. However, the similar behavior of H_{eb} for the 40 and 60 nm NiO layers is inconsistent with the assumption that the AF grains are monodomain. This suggests that the mechanism of exchange biasing is more complex than described by the Fulcomer–Charap model, e.g., by the formation of AF domain walls in the AF grains as proposed by more recent models.^{9–11} We note, however, that the detailed nature of the exchange biasing mechanism is not important for the general assumptions on which the macroscopic two-level relaxation model is based.

An new effect of the relaxation process is demonstrated by field cooling from above T_B to 290 K in 2 min instead of 10 h, which results in a decrease of H_{eb} from 12 to 9 kA/m. This effect does not only support the relaxation model, but also shows the importance of using a sufficiently low cooling rate to obtain exchange biasing in spin valve devices when using a magnetic anneal treatment.

Thermal fluctuation aftereffect of exchange coupled films for spin valve devices

Junichi Fujikata,^{a)} Kazuhiko Hayashi, Hidefumi Yamamoto, and Masafumi Nakada
Functional Devices Research Laboratories, NEC Corporation, 1-10 Nisshin-cho, Fuchu-city, Tokyo 183,
Japan

The annealing-time-dependent change in the unidirectional anisotropy field for exchange coupled films with FeMn, PdPtMn, NiMn, and NiO, which are generally used for spin valve, was investigated after thermal annealing below their blocking temperatures. It was shown that the distribution of local blocking temperature was similar for each exchange coupled film. The annealing-time-dependent change in the unidirectional anisotropy was explained by the use of thermal fluctuation aftereffect model, and the relaxation time for the anisotropy change was found to be much larger for FeMn than for PdPtMn, NiMn, and NiO, when normalizing annealing temperature by their blocking temperatures. From the viewpoint of device application, however, NiMn was proven to be the most promising antiferromagnet in terms of thermal stability because of its highest blocking temperature. © 1998 American Institute of Physics. I. INTRODUCTION

Thermal stability of unidirectional anisotropy of pinned layers for spin valve films is very important for magnetoresistive head application, and studying the annealing-time-dependent change in unidirectional anisotropy is very useful for estimating device lifetime. With respect to the thermal stability of the exchange coupled films, the temperature dependence of exchange coupling field (H_{ex}) has been reported, and Fulcomer and Charap have explained this dependence based on thermal fluctuation theory.¹ Tsang, Speriosu *et al.*, and Soeya *et al.* have reported that FeMn/NiFe and NiO/NiFe films have a variety of exchange paths, and that local exchange anisotropy rotates at local blocking temperature.²⁻⁴ Nishioka *et al.* investigated how the grain size of antiferromagnets affects temperature dependence of exchange coupling for a FeMn/NiFe system, based on thermal fluctuation theory.⁵

In this study, exchange coupled films with FeMn, PdPtMn,⁶ NiMn, and NiO, which are generally used for spin valves, were annealed below the blocking temperatures (T_B), and their annealing-time-dependent change in exchange anisotropy was investigated. Experimental results were compared with those obtained in a thermal fluctuation after effect model.

II. EXPERIMENT

Ferromagnetic/antiferromagnetic bilayer films of $\text{Ni}_{81}\text{Fe}_{19}$ (15nm)/ $\text{Ni}_{50}\text{Mn}_{50}$ (30 nm), $\text{Ni}_{81}\text{Fe}_{19}$ (10 nm)/ $\text{Pd}_{17}\text{Pt}_{32}\text{Mn}_{51}$ (30 nm), $\text{Ni}_{81}\text{Fe}_{19}$ (6 nm)/ $\text{Fe}_{50}\text{Mn}_{50}$ (15 nm), and NiO (50 nm)/ $\text{Ni}_{81}\text{Fe}_{19}$ (6 nm) were prepared on glass substrates by rf and dc magnetron sputtering. The argon sputtering pressure was 3.0×10^{-1} Pa. To prevent oxidation, 10 nm of Ta capping layers were deposited for each film. They were annealed at 270 °C for 15 h for NiFe/NiMn, 270 °C for 5 h for NiFe/PdPtMn, and 200 °C for 1 h for

NiFe/FeMn under pressures of less than 2.0×10^{-4} Pa with a dc applied magnetic field of 500 Oe to induce unidirectional anisotropy.

The thermal stability of exchange coupled films with the antiferromagnets, NiMn, PdPtMn, FeMn, and NiO was studied by measuring the exchange anisotropy field (H_{ex}) at room temperature (RT) after thermal annealing below their blocking temperatures with a magnetic field of 500 Oe applied, antiparallel to their easy axes. Magnetization was obtained using a vibrating sample magnetometer (VSM). The crystalline structure and grain size of exchange coupled films was analyzed by x-ray diffraction (XRD) and cross sectional TEM.

III. RESULTS AND DISCUSSION

A. Exchange anisotropy rotation

Figures 1(a)–1(d) show H_{ex} dependence on temperature. T_B of NiFe/FeMn, NiFe/PdPtMn, NiFe/NiMn, and NiO/NiFe is about 160, 330, 360, and 200 °C. The exchange coupling energy for each system is 0.14, 0.18, 0.13, and 0.07 mJ/m² at RT, which are comparable to those reported by other groups.^{6,7} The average grain size for each manganese antiferromagnet is about 7 to 8 nm, and for NiO it is about 10 nm with columnar structures. The dotted lines show the exchange anisotropy change below the blocking temperature when exchange coupled films are annealed with a magnetic field of 500 Oe applied, antiparallel to the easy axes. The local exchange anisotropy of all exchange coupled films rotates below the blocking temperature, which shows they have a broad distribution of local blocking temperature, and the spin directions of antiferromagnetic grains rotate at the local blocking temperature.^{3,4}

Figure 2(a) shows H_{ex} dependence on annealing temperature. H_{ex} is normalized by the value at RT. H_{ex} decreases gradually with increasing annealing temperature, indicating that the local blocking temperature is distributed below the blocking temperatures for each exchange coupled film. Fig-

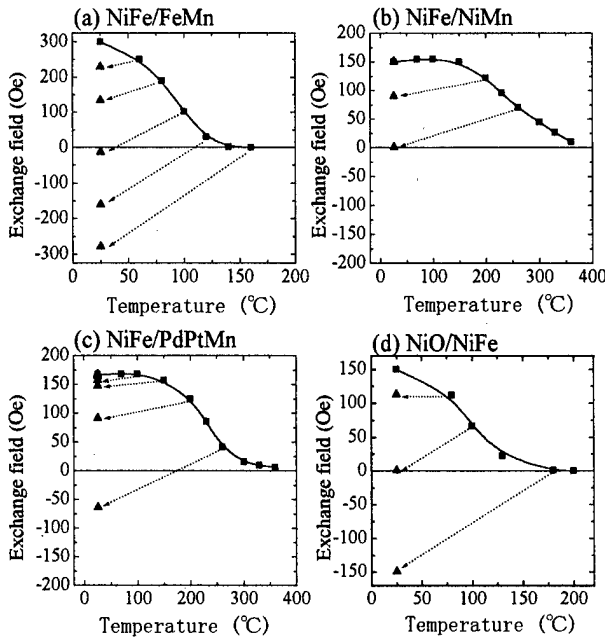

FIG. 1. Exchange field dependence on temperature for (a) NiFe/FeMn, (b) NiFe/NiMn, (c) NiFe/PdPtMn, and (d) NiO/NiFe. The dotted lines shows exchange field change by thermal annealing below the blocking temperature.

ure 2(b) shows H_{ex} dependence on annealing temperature normalized by the respective blocking temperatures. H_{ex} dependence on normalized annealing temperature is very similar for each exchange coupled film, which shows that the distribution of local blocking temperatures is similar for each exchange coupled film, under the assumption that the distri-

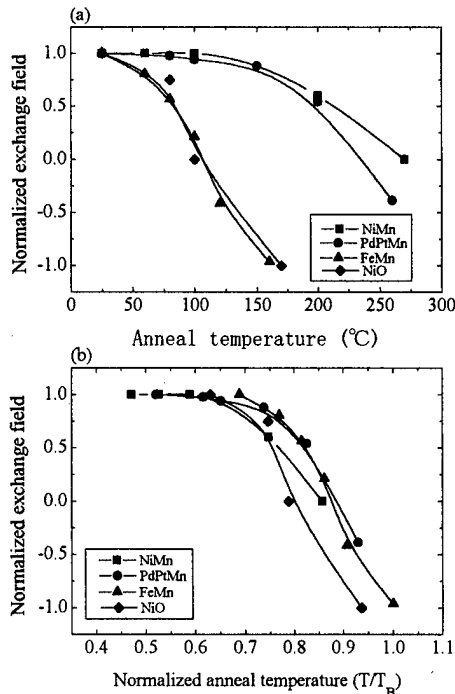

FIG. 2. (a) Normalized exchange field dependence on annealing temperature. (b) Normalized exchange field dependence on normalized annealing temperature (T/T_B).

bution of local blocking temperature corresponds to the distribution of exchange coupling energy.

B. Annealing-time-dependent change model for H_{ex}

We studied the annealing-time-dependent change in H_{ex} for exchange coupled films. A thermal fluctuation aftereffect model is assumed^{1,5} and results obtained with it are compared with experimental results. For simplicity, both ferromagnet and antiferromagnet are assumed to have uniaxial anisotropies with their easy axes, parallel to the X direction. The total energy of the antiferromagnetic layer is expressed by

$$U = \sum S_i [K_u D_i \sin^2 \theta_i - J_{ex} \cos(\theta_i - \varphi)]. \quad (1)$$

Here, K_u is the magnetic anisotropy constant of the antiferromagnetic grain, and J_{ex} is the exchange coupling constant. S_i and D_i are the interface area and the height of the antiferromagnetic grain. θ_i is the angle between the $+X$ direction and the interface magnetic moment of the i th antiferromagnetic grain, and φ is the angle between the $+X$ direction and the ferromagnetic moment.

E_{exi} and H_{ai} are introduced by

$$E_{exi} = J_{ex} S_i, \quad (2)$$

$$H_{ai} = K_u S_i D_i. \quad (3)$$

In this study, the ferromagnetic moment is antiparallel to the easy axis, and substituting φ for π , the energy of i th antiferromagnetic grain (U_i) is expressed by

$$U_i = H_{ai} \sin^2 \theta_i + E_{exi} \cos \theta_i, \quad (4)$$

$$\begin{aligned} dU_i/d\theta_i &= 2H_{ai} \sin \theta_i \cos \theta_i - E_{exi} \sin \theta_i \\ &= 2H_{ai} \sin \theta_i (\cos \theta_i - E_{exi}/2H_{ai}). \end{aligned} \quad (5)$$

When H_{ai} is larger than $E_{exi}/2$, the energy profile shows two local minimums at $\theta=0$ and π , respectively. The energy of the barrier is written as

$$E_{bi} = H_{ai} [1 + (E_{exi}/H_{ai})^2/4]. \quad (6)$$

Therefore, $p_{i+}(t)$ and $p_{i-}(t)$ are determined by their initial values and thermal excitation of the particles. [p_{i+} : the probability of the i th grain at higher minimum energy ($\theta=0$), p_{i-} : the probability of the i th grain at lower minimum energy ($\theta=\pi$)]. The main equations to determine them may be written as follows:

$$\begin{aligned} dp_{i-}/dt &= \nu_0 \{ p_{i+} \exp[-(E_{bi} - E_{exi})/(kT)] \\ &\quad - p_{i-} \exp(-E_{bi} + E_{exi})/(kT) \} \end{aligned} \quad (7)$$

$$p_{i+} + p_{i-} = 1 \quad (8)$$

(ν_0 : trial number per second to overcome the barrier).

Solving Eqs. (7) and (8), we get

$$p_{i-}(t) = p_L^{\text{inf}} [1 - \exp(-t/\tau_i)] + (1 - p_{0+}) \exp(-t/\tau_i). \quad (9)$$

Here, $p_L^{\text{inf}} = p_{i-}(t=\infty)$, the probability of the i th grain at the lower minimum energy at equilibrium, and τ_i , the relaxation time, are expressed by

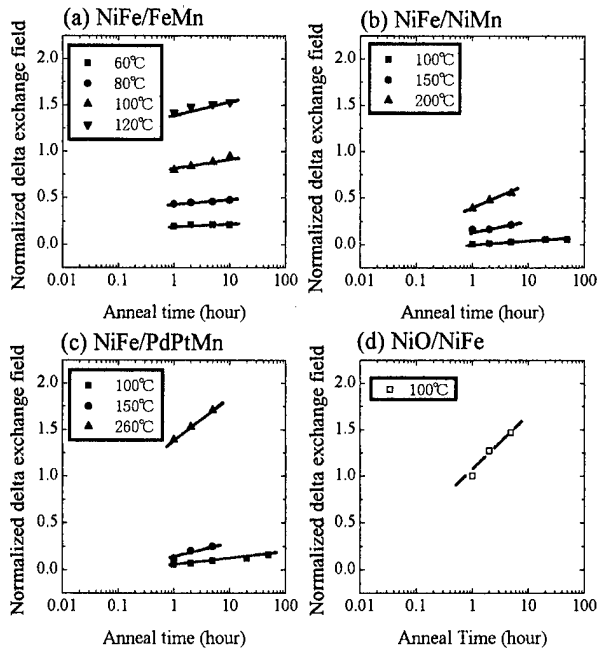

FIG. 3. Dependence of normalized exchange field change on annealing time for (a) NiFe/FeMn, (b) NiFe/NiMn, (c) NiFe/PdPtMn, and (d) NiO/NiFe.

$$p_L^{\text{inf}} = 1 / \{1 + \exp[-2E_{\text{ex}} / (kT)]\} \quad (10)$$

$$1/\tau_i = \nu_0 \{ \exp[-(E_{\text{bi}} - E_{\text{exi}}) / (kT)] + \exp[-(E_{\text{bi}} + E_{\text{exi}}) / (kT)] \}. \quad (11)$$

In this study, the initial value of p_{0+} is nearly equal to 1 and p_L^{inf} is nearly equal to 1 at equilibrium. Therefore, Eq. (9) is expressed by

$$p_{i-}(t) = 1 - \exp(-t/\tau_i). \quad (12)$$

Here, we introduce the distribution of the relaxation time for spin rotation, which arises from the distribution of grain size in the antiferromagnetic layer. The distribution function is assumed to be expressed by

$$\int g(\tau) / \tau d\tau = 1. \quad (13)$$

When $g(\tau)$ is assumed to be uniform between τ_{min} and τ_{max} (that is, the distribution of grain size in the antiferromagnetic layer is assumed to be uniform between maximum grain size and minimum grain size), the annealing-time-dependent change of H_{ex} is expressed by⁸

$$\begin{aligned} \Delta H_{\text{ex}} &= 2 \sum E_{\text{exi}} p_{i-} / M_s V_m \\ &\doteq 2 H_{\text{ex0}} \left\{ 1 - \int [g(\tau) / \tau] e^{-t/\tau} d\tau \right\} \\ &= 2 H_{\text{ex0}} [1 + (-\ln \tau_{\text{max}} + 0.577 + \ln t) / \ln(\tau_{\text{max}} / \tau_{\text{min}})] \end{aligned} \quad (14)$$

(M_s , V_m : saturation magnetization and volume of the ferromagnet). Therefore, the annealing-time-dependent change in H_{ex} is expressed by

$$\Delta H_{\text{ex}} / H_{\text{ex0}} = h + K \ln(t) \quad (15)$$

FIG. 4. Coefficient K dependence on normalized annealing temperature (T/T_B).

(ΔH_{ex} : change in exchange field, H_{ex0} : initial exchange field, h : rapid decrease term of H_{ex} caused by the distribution of local blocking temperature, K : coefficient for annealing-time-dependent change in H_{ex}).

That is, the annealing-time-dependent change in H_{ex} is explained by thermal fluctuation aftereffect and is proportional to the logarithm of annealing time.

C. Experimental results for annealing-time-dependent change in H_{ex}

Figures 3(a)–3(d) shows the change rate of the H_{ex} dependence on annealing time. Experimental results agree well with those obtained with the thermal fluctuation aftereffect model, and the annealing-time-dependent change in H_{ex} is proportional to the logarithm of annealing time. The slope versus logarithm of annealing time (coefficient K) increases with an increase in annealing temperature, because exchange anisotropy rotation arises from thermal fluctuation. For NiO/NiFe films, H_{ex} change rate dependence on annealing time is strong. Figure 4 shows coefficient K dependence on annealing temperature. In Fig. 4, annealing temperature is normalized by T_B . Coefficient K increases with increasing annealing temperature, and different antiferromagnets have different K values. It is shown that K is much smaller for FeMn than for NiMn, PdPtMn, and NiO. That is, the energy barrier for anisotropy rotation is larger for FeMn than that for NiMn, PdPtMn, and NiO, when annealing temperature is normalized by the respective blocking temperatures of the materials. Taking these blocking temperatures into account, however, the rate of decrease in H_{ex} for NiMn/NiFe is estimated to be no more than 20% after 10^5 hours of annealing at 100 °C, while for FeMn/NiFe it is 150%. From the viewpoint of device application, therefore, NiMn is proven to be the most promising antiferromagnet in terms of thermal stability.

$\text{MgO}/\text{Cr}_{70}\text{Al}_{30}/\text{Fe}_{19}\text{Ni}_{81}$ and $\text{ZnO}/\text{Cr}_{70}\text{Al}_{30}/\text{Fe}_{19}\text{Ni}_{81}$ layered films with different buffer layer thicknesses were prepared on (100)Si substrates in order to investigate the relationship among the exchange-coupling field, the grain size, and the lattice constant of the antiferromagnetic layer. The exchange-coupling field was found to consist of the intragrain exchange coupling and the intergrain coupling fields. The former field is inversely proportional to the product of the lattice constant and the grain size. The latter field is constant and changes its sign in association with the increase of the buffer layer thickness. [S0021-8979(98)48311-7] © 1998 American Institute of Physics.

I. INTRODUCTION

Unidirectional anisotropy induced by the exchange coupling between ferromagnetic and antiferromagnetic layers is useful for stabilizing ferromagnetic domain structures in magnetoresistive sensors and spin valve heads. For these applications, a variety of antiferromagnetic/ferromagnetic bilayers such as $\text{MnFe}/\text{Fe-Ni}$, $\text{NiMn}/\text{Fe-Ni}$, $\text{NiO}/\text{Fe-Ni}$, and $\text{CrMnPt}/\text{Fe-Ni}$ have been intensively investigated.¹⁻⁵

Recently we have found that $\text{Cr}_{70}\text{Al}_{30}$ alloy is promising as an antiferromagnetic layer for the exchange-coupled bilayer because of its high Néel temperature of 900 K,⁶ high corrosion resistance, and high electrical resistivity of 1300 $\mu\Omega\text{ cm}$ at room temperature. Our previous studies showed that the exchange-coupling field of $\text{Cr}_{70}\text{Al}_{30}/\text{Fe}_{19}\text{Ni}_{81}$ bilayers ranges about 100 Oe and is inversely proportional to the product of the antiferromagnetic grain size and the lattice constant.^{7,8}

In the present study, MgO (or ZnO)/ $\text{Cr}_{70}\text{Al}_{30}/\text{Fe}_{19}\text{Ni}_{81}$ layered films with different buffer layer thicknesses were prepared to alter the crystallographic states in the antiferromagnetic layer such as the grain size and the lattice constant. The effects of the crystallographic states on the exchange-coupling field are discussed in terms of the intergrain coupling.

II. EXPERIMENT

MgO (or ZnO)/ $\text{Cr}_{70}\text{Al}_{30}/\text{Fe}_{19}\text{Ni}_{81}$ layered films were deposited on (100)Si substrates by a magnetron sputter deposition method. The MgO or ZnO buffer layer was first deposited with a rf power of 200 W, and then $\text{Cr}_{70}\text{Al}_{30}/\text{Fe}_{19}\text{Ni}_{81}$ bilayers were deposited with a dc power of 30 W. The MgO

buffer layer thickness was varied from 0 to 1000 Å, while the ZnO buffer layer thickness was varied from 0 to 500 Å. The base pressure before the deposition was 4×10^{-7} Torr. Argon pressure during the deposition was 4×10^{-3} Torr for the buffer layers and the following bilayers. A magnetic field of 300 Oe was applied during the deposition. No postannealing was carried out.

Magnetization measurements were performed by a vibrating sample magnetometer (VSM). The exchange-coupling field H_{ex} was defined as the shift of the hysteresis loop along the applied field axis. The crystal structure, the grain size, and the lattice constant were examined by x-ray ($\text{Cu K}\alpha$) diffractometry.

III. RESULTS AND DISCUSSION

The exchange-coupling field H_{ex} appears when the $\text{Cr}_{70}\text{Al}_{30}$ layer thickness reaches about 300 Å. This critical thickness is much thicker than that for MnFe (~ 50 Å),³ suggesting that the magnetocrystalline anisotropy of the $\text{Cr}_{70}\text{Al}_{30}$ layer is relatively small, and the $\text{Cr}_{70}\text{Al}_{30}$ layer cannot sustain a single antiferromagnetic domain structure. The exchange-coupling field H_{ex} is thus considered to appear when the antiferromagnetic layer is thick enough to accommodate an antiferromagnetic domain wall parallel to the film surface. In other words, the antiferromagnetic/ferromagnetic interfacial exchange coupling energy arises from the formation of the antiferromagnetic domain wall. Therefore we fixed the antiferromagnetic $\text{Cr}_{70}\text{Al}_{30}$ layer thickness at 1000 Å, and varied the MgO or ZnO buffer layer thickness in order to change the grain size and the lattice constant of the $\text{Cr}_{70}\text{Al}_{30}$ layer. The x-ray diffraction analyses show that the

FIG. 1. (a) The grain size D and (b) the lattice constant a as a function of buffer layer thickness t_{buffer} for the antiferromagnetic $\text{Cr}_{70}\text{Al}_{30}$ layer in MgO (●) [or ZnO (○)]/ $\text{Cr}_{70}\text{Al}_{30}$ / $\text{Fe}_{19}\text{Ni}_{81}$ layered films.

$\text{Cr}_{70}\text{Al}_{30}$ layer has a bcc structure and that no clear preferential orientation is obtained for all the thicknesses of the buffer layers.

Figures 1(a) and 1(b) show the grain size D and the lattice constant a of the antiferromagnetic $\text{Cr}_{70}\text{Al}_{30}$ layer as a function of buffer layer thickness t_{buffer} . The grain size D was evaluated by Scherrer's equation. For both MgO and ZnO buffer layers, the values of D sharply increase with t_{buffer} and are almost saturated at around $t_{\text{buffer}} \approx 100$ Å. In the case of the MgO buffer layer, the value of D again increases gradually above $t_{\text{buffer}} \approx 500$ Å. On the other hand, the values of a for both MgO and ZnO buffer layers seem saturated above $t_{\text{buffer}} \approx 100$ Å, indicating that the lattice strain at the interface between the buffer layer and the $\text{Cr}_{70}\text{Al}_{30}$ layer is released with increasing t_{buffer} .

These variations clearly reflect on the exchange-coupling field H_{ex} and the coercive field H_c as shown in Figs. 2(a) and 2(b). The variations of H_{ex} and H_c are quite similar. For the films with the MgO buffer layer, both H_{ex} and H_c decrease remarkably up to $t_{\text{buffer}} \approx 100$ Å followed by gradual increase

FIG. 2. (a) The exchange-coupling field H_{ex} and (b) the coercive field H_c as a function of buffer layer thickness t_{buffer} for MgO (●) [or ZnO (○)]/ $\text{Cr}_{70}\text{Al}_{30}$ / $\text{Fe}_{19}\text{Ni}_{81}$ layered films.

FIG. 3. H_{ex} vs $(M_s t_f a D)^{-1}$ plot for MgO (●) [or ZnO (○)]/ $\text{Cr}_{70}\text{Al}_{30}$ / $\text{Fe}_{19}\text{Ni}_{81}$ layered films with different buffer layer thickness t_{buffer} .

at around $t_{\text{buffer}} \approx 500$ Å. For the ZnO buffer layer, no gradual increase at $t_{\text{buffer}} \approx 500$ Å was observed.

In our previous study,⁸ we have shown that the exchange-coupling field is given by the sum of the intrinsic intragrain exchange-coupling field $H_{\text{ex}}^{\text{in}}$ and the extrinsic intergrain coupling field H_g . Since the $\text{Cr}_{70}\text{Al}_{30}$ layer is polycrystalline solid solution, the random field approximation⁹ was applied to evaluate the intrinsic exchange-coupling field $H_{\text{ex}}^{\text{in}}$ from the microscopic exchange energy at the interface J_i . Taking the grain size D as a characteristic length of the exchange-coupling area, the effective exchange-coupling energy J_{eff} is given by $J_{\text{eff}} = f_i J_i / \sqrt{N} = f_i a J_i / D$, where N is the number of exchange coupled spin pairs at the interface plane, f_i is the structural parameter of order unity, and a is the lattice constant of the antiferromagnetic layer. The intrinsic exchange-coupling field $H_{\text{ex}}^{\text{in}}$ is thus given by $H_{\text{ex}}^{\text{in}} = f_i J_i / M_s t_f a D$, where M_s is the saturation magnetization of the ferromagnetic layer and t_f is the thickness of the ferromagnetic layer. This shows that $H_{\text{ex}}^{\text{in}}$ is inversely proportional to $M_s t_f a D$. On the other hand, the extrinsic intergrain coupling field H_g is caused by the intergrain coupling which arises from the coupling between the antiferromagnetic grains through the grain boundaries or the ferromagnetic layer.

Using the obtained values of D and a , H_{ex} was plotted against $(M_s t_f a D)^{-1}$ in Fig. 3. All the values of H_{ex} are categorized into two lines with the same inclination which gives a reasonable magnitude of the microscopic exchange energy $J_i = 9.3 \times 10^{-16}$ erg. This value is in good agreement with the exchange energy evaluated from the Néel temperature of $\text{Cr}_{70}\text{Al}_{30}$. The value of H_g is negative (-20 ± 1 Oe) when the thickness t_{buffer} is lower than 200 Å, whereas it is positive ($+21 \pm 1$ Oe) when the thickness t_{buffer} is in the range from 200 to 1000 Å. This behavior is purely originated from the crystallographic states of the $\text{Cr}_{70}\text{Al}_{30}$ layer, because the same tendencies were observed, regardless of the kind of buffer layer. As mentioned above, therefore, the origin of H_g is the intergrain coupling through the antiferro-

FIG. 4. The exchange-coupling field H_{ex} as a function of ferromagnetic layer thickness t_f for MgO/Cr₇₀Al₃₀/Fe₁₉Ni₈₁ layered films with different buffer layer thickness t_{buffer} .

magnetic grain boundaries or through the ferromagnetic layer.

In order to make this point clearer, Cr₇₀Al₃₀/Fe₁₉Ni₈₁ bilayers with different Fe₁₉Ni₈₁ thicknesses ($t_f = 30, 50, 80$, and 100 Å) were prepared on MgO buffer layers of 1000 or 100 Å. As shown in Fig. 4, the value of H_{ex} varies inversely proportional to the thickness t_f in keeping with the relationship that the exchange-coupling field H_{ex} for the thicker MgO buffer layer is larger than that for the thinner one by $2H_g$. By using the data in Fig. 4, $M_s H_{ex} t_f$ vs $M_s t_f$ plot was then carried out in Fig. 5. Since the relationship between the intrinsic and extrinsic exchange energies is given by $M_s H_{ex} t_f = f_i J_i / aD + M_s H_g t_f$, the value and sign of H_g can be determined as slopes from the $M_s H_{ex} t_f$ vs $M_s t_f$ plot. It should be noted that the first intrinsic energy term is constant

FIG. 5. $M_s H_{ex} t_f$ vs $M_s t_f$ plots for MgO(1000 Å)/Cr₇₀Al₃₀(1000 Å)/Fe₁₉Ni₈₁(50 Å) layered films (●), and MgO(100 Å)/Cr₇₀Al₃₀(1000 Å)/Fe₁₉Ni₈₁(100 Å) layered films (○).

for the fixed buffer layer thickness since the antiferromagnetic grain size and the lattice constant are the same. The values of $f_i J_i / aD$ are 15×10^{-2} erg/cm² for $t_{buffer} = 1000$ Å and 18×10^{-3} erg/cm² for $t_{buffer} = 100$ Å. Two linear lines are clearly observed with positive ($+19$ Oe) and negative (-18 Oe) slopes, indicating that the transition from the negative H_g to the positive H_g occurs with increasing the antiferromagnetic grain size D . This implies that when the MgO buffer layer is thin, the antiferromagnetic Cr₇₀Al₃₀ grains weakly couple through the grain boundaries, suppressing the formation of the antiferromagnetic domain wall. On the contrary, the antiferromagnetic grain growth associated with the increase of the buffer layer thickness t_{buffer} leads to a magnetically separated antiferromagnetic configuration, encouraging the formation of the antiferromagnetic domain wall during the magnetization reversal. Although the above explanation describes the trend of the transition, it is difficult to explain the origin of the positive H_g . This requires further study.

In conclusion, the exchange-coupling mechanism of the MgO (or ZnO)/Cr₇₀Al₃₀/Fe₁₉Ni₈₁ layered films with different buffer layer thicknesses was investigated in connection with the crystallographic states in the antiferromagnetic layer. The grain size and the lattice constant of the Cr₇₀Al₃₀ layer were significantly varied with the thickness of the buffer layer. The exchange-coupling field was found to consist of the intragrain intrinsic exchange-coupling field and the intergrain exchange-coupling field. The former is inversely proportional to the product of the lattice constant and the grain size. The latter changes its sign from negative to positive when the thickness of the buffer layer exceeds 200 Å.

Magnetic, temperature, and corrosion properties of the NiFe/IrMn exchange couple

A. J. Devasahayam, P. J. Sides, and M. H. Kryder

Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Exchange biasing properties of the NiFe/IrMn exchange couple were investigated by varying the IrMn composition and sputtering conditions. At a composition of Ir₂₀Mn₈₀ an exchange field of ~ 60 Oe and a coercivity of 8 Oe were obtained for the structure Si/Ta-75 Å/NiFe-250 Å/IrMn-500 Å. The maximum exchange field obtained was similar for rf diode, rf magnetron, and dc magnetron sputtering of the IrMn. X-ray diffraction measurements showed that the crystalline texture was (111) for both the NiFe and IrMn, but a strong crystalline texture did not necessarily correspond to a large exchange field. The interfacial exchange energy, J_k , was evaluated to be 0.145 erg/cm² and the minimum thickness of IrMn needed to support an exchange field was 75 Å. The blocking temperature was measured to be a function of the IrMn thickness and was in the range of 220–250 °C for thicknesses >200 Å. Below this, the blocking temperature rapidly decreased to a value of 130 °C at 75 Å of IrMn. Corrosion testing was done in a Battelle Class II type corrosive environment. Using the exchange field as a figure of merit, it was found that the IrMn corrosion properties were only slightly better than FeMn, and significantly worse than NiMn and CoNiO. We were also able to successfully fabricate NiFe based spin-valves pinned with IrMn and they show good magnetic properties. Our results show that IrMn is a good alternative to FeMn. © 1998 American Institute of Physics. [S0021-8979(98)18211-7]

I. INTRODUCTION

FeMn and NiO are the most commonly used antiferromagnetic exchange biasing materials.^{1,2} However, neither of them are ideal. FeMn has both poor corrosion resistance and poor temperature stability with a blocking temperature of 150 °C. NiO fares much better in these two areas, but has a low interfacial exchange energy of 0.059 erg/cm² which renders it unsuitable for high density, narrow track width applications. IrMn is a possible alternative material which was reported to have a good combination of exchange fields, corrosion resistance and temperature stability when coupled with Co₉₀Fe₁₀.³

In this article, the magnetic properties of IrMn when exchange coupled to NiFe are examined as a function of composition and sputtering parameters. The temperature stability was also investigated with respect to IrMn thickness. Corrosion properties were measured in an environmental chamber and compared with FeMn, CoNiO, and NiMn. Finally, NiFe based spin-valve structures were fabricated with IrMn as the exchange pinning material, and these showed good magnetic properties.

II. EXPERIMENTAL PROCEDURE

IrMn was deposited from a Mn target with Ir chips bonded to it. The number of Ir chips attached was adjusted in order to obtain optimum magnetic properties. These properties were characterized with a $B-H$ loop tracer and vibrating sample magnetometer. Rf diode sputtered films were deposited in a unidirectional field of 35 Oe to define the pinning direction. Magnetron sputtered films had no external fields applied. Crystallographic properties were measured with a x-ray diffractometer and compositional information was obtained with an Energy Dispersive X-ray Fluorescence ma-

chine. Corrosion measurements were done in a Battelle Class II environmental chamber previously described.⁴

III. RESULTS AND DISCUSSION

A. Magnetic properties

Good exchange biasing properties of the NiFe/IrMn couple were obtained when the IrMn films deposited were in the antiferromagnetic phase. This corresponds to an Ir content in the range of 16–32 at. %. The Ir₂₀Mn₈₀ composition had the highest exchange fields as shown in Fig. 1(a).

The biasing properties were further optimized by varying the sputtering conditions. In all these experiments, the NiFe thickness was kept constant at 250 Å. A strong (111) texture for NiFe and IrMn was observed as is plotted in the x-ray scan in Fig. 1(b). The (111) peak of IrMn occurs at an angle $2\theta=41.52^\circ$, which corresponds to a lattice constant, a , of 3.76 Å.

The effect of varying the deposition pressure while keeping the power constant at 250 W is shown in Fig. 2. Also plotted in that figure is the (111) peak intensity, in counts, of the IrMn layer, which indicates the strength of this texture.

FIG. 1. (a) H_e and H_c for samples with different compositions sputtered at 250 W rf power and (b) a typical x-ray scan of a NiFe/Ir₂₀Mn₈₀ sample.

The plot shows that the exchange field (H_e) increases with increasing sputtering pressure to a maximum of 37 Oe at 30 mT of pressure. The (111) peak intensity of IrMn does not show a clear correlation with the exchange field. It does appear that a poor (111) texture corresponds to a large exchange field. Substrate bias is undesirable for good exchange properties, since zero bias yields the largest exchange field as shown in Fig. 3. Also, poor (111) crystalline texture of the IrMn is seen at zero bias. The exchange field increases as the sputtering power decreases and reaches a maximum of 55 Oe at 50 W of power as illustrated in Fig. 4. The IrMn (111) peak intensity seems to generally follow the opposite trend, increasing in intensity with increasing power. It can be concluded that low power, high pressure and zero substrate bias are desirable for good exchange fields, while strong (111) texture for IrMn does not correspond to good biasing fields. These samples also had coercivities of 4–12 Oe.

The effect of using magnetron sputtering instead of the previously used rf diode sputtering was studied with samples of the same structure. Optimizing the sputtering conditions for both rf and dc magnetron sputtering yielded a maximum exchange field of 57 and 62 Oe, respectively. These values are similar to those obtained with rf diode sputtering.

A minimum thickness of 75 Å of IrMn is needed for a large exchange field to be observed as shown in Fig. 5(a). Above this value, the exchange field reaches a peak of about 58 Oe with 200 Å and then gradually decreases on increasing the IrMn thickness. This is a commonly observed trend with exchange biasing materials. The exchange fields also follow the usual inverse relationship with the thickness of NiFe as illustrated in Fig. 5(b). By fitting a $1/t$ curve to the data, an interfacial exchange energy, J_k , of 0.145 erg/cm² is calculated. This value is larger than that of NiO, CoNiO, and NiMn as-deposited, but lower than that obtained when NiMn is annealed.

B. Temperature properties

The blocking temperature was measured for several samples, with different IrMn thicknesses and these results are plotted in Fig. 6(a). In this figure, the exchange field for each sample is normalized to the original exchange field obtained at room temperature. This value decreases monotonically for all the samples. For thicknesses of 200 Å and above, the plotted lines are virtually the same leading to a blocking temperature in the range of 200–250 °C. Below this thickness of IrMn, the blocking temperature falls off and is about 130 °C for a 75 Å IrMn film. This trend is plotted in Fig. 6(b) and can be explained in terms of a “finite size effect.” The phenomenon arises out of the finite size of the system which bounds the correlation length⁵ and can be described by a simple scaling law shown in Eq. (1). In this equation, T_B is the blocking temperature, t is the thickness of IrMn, C_0 is the correlation length at $T=0$ K, and λ is the shift exponent for finite size scaling:⁶

$$\frac{T_B(\infty) - T_B(t)}{T_B(\infty)} = \left(\frac{C_0}{t} \right)^\lambda. \quad (1)$$

Assuming $T_B(\infty) = 523$ K (250 °C), $[1 - T_B/T_B(\infty)]$ is plot-

ted versus the IrMn layer thickness in a log-log plot shown in Fig. 7. The linear curve fit yields a value of 1.5 for λ , which is close to the theoretical value.⁶

C. Corrosion measurements

The corrosion resistance measurements were done in a Battelle Class II type of environment. The samples were exposed to the pollutants in an impinging jet configuration which was designed to have good uniformity of exposure of the sample surface to the pollutants. The parameters of the experiment are noted in the table inset of Fig. 8. Samples were cut into equal sizes to minimize any skewing of the data due to size effects. The exchange field was used as the figure of merit and was measured after successive exposures in the chamber. The sample structure used was: substrate/NiFe-250 Å/exchange material-500 Å. The exchange materials tested were FeMn, NiMn, CoNiO, and IrMn. The normalized exchange field vs exposure time is shown in Fig. 8. From the figure, it can be seen that CoNiO has the best corrosion properties, showing no degradation over the entire exposure time of 140 h. NiMn is second best, showing very little deterioration of the exchange field up to 40 h of exposure at which point the IrMn and FeMn provide almost no exchange bias. Between 15 and 40 h of exposure, the IrMn out performs the FeMn. As a comparison, metal-evaporated tape has a similar corrosion resistance, in terms of magnetic moment reduction over time, as does NiMn.⁴

D. NiFe based IrMn pinned spin-valves

NiFe based spin valves with an IrMn pinning layer were fabricated with and without Co to enhance the GMR effect. The large pinning field of IrMn is illustrated in the hysteresis loop of a NiFe spin valve shown in Fig. 9(a). In this case, a pinning field of 650 Oe was obtained for 29 Å of NiFe. The

FIG. 8. Normalized H_e vs exposure time for several exchange couples with the structure substrate/NiFe-250 Å/exchange material-500 Å.

FIG. 9. (a) MH Loop of a spin valve with the structure Ta/NiFe-67 Å/Cu-27 Å/NiFe-29 Å/IrMn-125 Å. (b) MR loop of the free layer of a Co enhanced spin valve with the structure Ta/NiFe-47 Å/Co-17 Å/Cu-24 Å/Co-13 Å/NiFe-22 Å/IrMn-200 Å.

MR response of a Co enhanced spin valve is shown in Fig. 9(b). The maximum MR value in this case, with Co on both Cu interfaces is 8.7%. NiFe only spin-valves and Co on the pinned layer/Cu interface spin-valves had MR ratios of 4.9% and 7.4%, respectively.

IV. SUMMARY

By varying the IrMn alloy composition and sputtering conditions, an exchange field of 60 Oe was obtained when $\text{Ir}_{20}\text{Mn}_{80}$ was coupled with 250 Å of NiFe. This corresponds to an interfacial exchange energy of 0.145 erg/cm². A minimum thickness of 75 Å of IrMn was needed in order to provide a large exchange. The blocking temperature was found to be a function of IrMn thickness and, this was explained in terms of a finite size effect. At thicknesses of IrMn > 200 Å, the blocking temperature was in the range of 220–250 °C. Corrosion measurements showed that IrMn was slightly less corrosive than FeMn, but worse than CoNiO and NiMn. NiFe based spin-valves fabricated with IrMn had an MR ratio as high as 8.7%. These spin-valves had a pinning field of 650 Oe for 29 Å of NiFe.

Our results show that IrMn has significantly superior temperature stability and exchange biasing properties when compared to FeMn. However, it has only marginally better corrosion resistance than FeMn. We have also found a dependence of the blocking temperature on the thickness of IrMn. Considering all these properties, IrMn appears to be a good alternative to FeMn for providing domain stabilization for MR heads and a pinning layer for spin-valve heads.

In order to study the antiferromagnetic (AFM) spin structure near the interface of exchange-biased bilayers, polarized neutron diffraction measurements were performed on a series of (111) Co (7.5 nm)/CoO (X nm) and CoO (X nm) thin films where $X=20, 40$, and 100 nm. In these samples, field cooling through the Néel temperature of the AFM increases the component of the CoO moment perpendicular to the applied field, relative to the parallel component. The subsequent application of a 500 Oe field perpendicular to the cooling direction rotates both the Co and CoO moments. Experiments on CoO films without Co showed a smaller difference between the parallel and perpendicular CoO moments in response to cooling and applied fields. Exchange coupling between the Co and CoO layers is apparently responsible for the increased projection of the AFM moments perpendicular to the cooling field. © 1998 American Institute of Physics. [S0021-8979(98)53011-3]

The term “exchange biasing” describes a phenomenon associated with interfacial coupling between ferromagnetic (FM) and antiferromagnetic (AFM) materials. In particular, a shift of the magnetic hysteresis loop along the field axis is observed after field cooling these composites through the Néel temperature of the AFM. Since its discovery over 40 years ago in oxidized Co particles,¹ a number of experimental studies^{2–6} have focused on layered systems because of their potential applications in magnetic sensors.⁷ Still unresolved, however, is the link between exchange biasing and the microscopic orientation of the spins in the AFM layer. Early theories^{1,8,9} assumed that the AFM spins at the interface couple collinearly to the FM layer. Alternately, Koon¹⁰ has suggested that the AFM and FM spins can align perpendicular depending on the interfacial structure. Takano *et al.*⁵ observed a correlation between the thermoremanent moment of polycrystalline CoO/MgO multilayers and the exchange biasing field of CoO/permalloy bilayers. This result suggested that uncompensated interfacial spins are the principal origin of exchange biasing in that system. Unfortunately, it is difficult to determine the AFM spin structures involved in exchange biasing because few experimental techniques can probe AFM order in buried and interfacial layers.

The scope of the present experiment is to determine the orientation of the AFM moments relative to the FM spins in (111) Co (7.5 nm)/CoO (X nm) thin films ($X=20, 40$, and 100 nm) using polarized neutron diffraction methods. After field cooling our epitaxial samples, we find that the percentage of CoO spins perpendicular to the field exceeds the percentage of parallel spins. The difference between the parallel and perpendicular AFM moment projections in the Co/CoO bilayers appears to be induced by proximity to the FM layer.

This behavior may arise from perpendicular coupling between the Co and CoO spins, as predicted by Koon.¹⁰

For this study, the CoO films were reactively sputtered at 100°C in 2 mTorr, of Ar and a small partial pressure of oxygen (0.09 mTorr) onto 1 in-diam (0001) Al_2O_3 substrates. We examined five single-layer and bilayer samples with differing compositions, SiO_2 (10 nm)/CoO (X)/ Al_2O_3 ($X=40$ and 100 nm) and SiO_2 (10 nm)/Co (7.5 nm)/CoO (X)/ Al_2O_3 ($X=20, 40$, and 100 nm). In order to induce exchange biasing and uniaxial anisotropy in the FM layer, the Co/CoO bilayers were deposited in a 300 Oe field applied along the [1120] Al_2O_3 in-plane axis. High-angle x-ray diffraction confirms that the CoO layers are epitaxial with (111) preferred orientation and are twinned in the growth plane.¹¹ Fits to x-ray reflectivity data for the Co/CoO (40 nm) bilayer indicate that the width of the Co/CoO interface is approximately 1.0 nm due to roughness or interdiffusion.

Magnetization measurements, performed in a superconducting quantum interference device (SQUID) magnetometer, reveal that exchange biasing is observed for a comparable epitaxial Co/CoO (100 nm) bilayer grown under similar conditions on a smaller substrate. Figures 1(a) and 1(b) show hysteresis loops at 10 and 200 K respectively after cooling in a 10 kOe field applied along the same direction as the growth field. Both the coercive field and the exchange-biasing field, H_{eb} , change as a function of temperature, as shown in Fig. 1. These field values are expected to differ for bilayers with thinner CoO and may depend on the film structure as determined by the substrate characteristics.

For these and related biased layers,¹² the temperature marking the onset of biasing is nearly equal to the Néel temperature, T_N , of the AFM component. Bulk CoO orders as a collinear antiferromagnet below $T_N=291$ K. The spins are ferromagnetically aligned in (111) sheets and are nearly perpendicular to a $\langle 111 \rangle$ axis. The moment direction alternates

FIG. 1. Magnetization as a function of field for a Co/CoO (100 nm) bilayer at (a) 10 K and (b) 200 K after field cooling from room temperature in a 10 kOe field applied along the in-plane easy axis.

in neighboring (111) planes.¹³ The CoO spins can thus align in any of four equivalent {111} domains. For our thin films, the [111] “propagation axis” of one of these domains is parallel to the growth directions. Due to twinning, however, there are six additional propagation axes tilted 70.5° from the [111] growth direction. Complementary neutron diffraction studies¹⁴ revealed that a large portion of the CoO spins reside in these six off-axis domains. We restricted our study to the characterization of those spins in the (111) growth-axis domain, which give rise to a $(1/2\ 1/2\ 1/2)$ magnetic reflection in our neutron data.

To characterize the AFM structure associated with the biased state in the Co/CoO bilayers, we performed polarized neutron diffraction measurements on these samples using the spin-polarized triple-axis spectrometer (SPINS) at the NIST Research Reactor. An electromagnet provided fields ranging from 50 to 2400 Oe. Since the maximum field is limited, we examined our samples at 200 K, rather than 10 K, in order to ensure saturation of the Co layer upon field cooling (Fig. 1). On the SPINS spectrometer, polarizing elements were positioned before and after the sample to select the spin direction of the incident and scattered neutrons. The polarization efficiencies were approximately 92%. For all scans through the $(1/2\ 1/2\ 1/2)$ CoO reflection, we measured both the non-spin-flip (NSF) and spin-flip (SF) scattered intensities. The NSF intensity is proportional to the square of the average CoO moment projection parallel to the vertical applied field, while the SF intensity is proportional to the square of the average moment projection perpendicular to the field.¹⁵ These moment projections may belong to the same or to different (111) domains.

Figure 2 shows typical scans through the $(1/2\ 1/2\ 1/2)$

FIG. 2. Polarized neutron diffraction scan through the $(1/2\ 1/2\ 1/2)$ reflection for a Co/CoO (100 nm) bilayer at 200 K. The wave vector Q is defined as $Q = (4\pi/\lambda)\sin\theta$ where the neutron wavelength $\lambda = 0.417$ nm and θ is the scattering angle. The shaded circles represent the NSF intensity and the open circles mark the SF intensity. The data in (a) were obtained after demagnetizing the sample and then cooling in zero field. The data in (b) were obtained in a 2200 Oe field after field cooling in -2200 Oe from room temperature. These data have not been corrected for the efficiencies of the polarizing elements.

reflection for the Co/CoO (100 nm) bilayer at 200 K. After cooling the sample in zero field, the NSF and SF intensities are approximately equal [Fig. 2 (a)]. These results are consistent with random orientation of the CoO spins within the growth plane. Upon cooling in a -2200 Oe field and measuring in a 2200 Oe field, the SF intensity increases slightly relative to the NSF as shown in Fig. 2(b). To determine if this difference is significant, we counted the NSF and SF intensities at the center of the $(1/2\ 1/2\ 1/2)$ reflection for extended times. Upon demagnetizing and zero field cooling, the ratio of the NSF to SF intensity is 1.001 ± 0.011 , compared to a ratio of 0.941 ± 0.017 for the same field preparation as in Fig. 2(b). However, a single-layer CoO (100 nm) film also gives a NSF/SF ratio of 0.94 ± 0.012 upon field cooling in 2400 Oe (Fig. 3). The AFM spins in the Co/CoO (100 nm) bilayer do not clearly show any effects from coupling to the FM Co layer. Since the data in Fig. 2 represent the CoO spin configuration averaged both along the growth axis and across the growth plane, the direction of the CoO moments near the Co/CoO interface cannot be directly distinguished from the direction of those moments in the remainder of the 100 nm layer. Any local deviations of the CoO spin direction at the Co/CoO interface may be masked by the bulk behavior of the thick AFM layer.

To determine if the perpendicular AFM spins are close to the interface, we measured the $(1/2\ 1/2\ 1/2)$ NSF and SF peak intensities for Co/CoO samples with thinner CoO layers. Initially cooling in zero field, the Co/CoO (40 nm) bilayer shows a tendency for perpendicular spin alignment (NSF/SF = 0.933 ± 0.01). Upon field cooling and measuring in 2400 Oe, the NSF/SF ratio of 0.873 ± 0.01 is significantly smaller than that for the Co/CoO (100 nm) sample, as shown in Fig. 3. This ratio varies only slightly up to 0.895 ± 0.011

FIG. 3. Ratio of the NSF to SF peak intensities for the $(1/2\ 1/2\ 1/2)$ CoO magnetic reflection as a function of CoO layer thickness for several Co/CoO and CoO samples, as marked. The samples were cooled to 200 K in a 2200–2400 Oe field and then measured in the same field. These data have not been corrected for background contributions or for the efficiencies of the polarizing elements. Background corrections would increase the ratio for the thinnest samples with the weakest intensities.

when the field is lowered to 150 Oe. Thus this spin configuration appears to “freeze in” upon field cooling. The average perpendicular projection of the CoO moment is at least 3% larger than the parallel projection. For the Co/CoO (20 nm) bilayer, a NSF/SF ratio of 0.928 ± 0.017 was measured in 2300 Oe after field cooling. This value is comparable to that for the Co/CoO (40 nm) bilayer. As shown in Fig. 3, the Co/CoO (20 nm) and Co/CoO (40 nm) films have a larger fraction of perpendicular spins than the Co/CoO (100 nm) film. This result may indicate that the canted spins are confined primarily to a finite region near the Co/CoO interface. For a more careful check of this hypothesis, the NSF/SF ratio should be accurately measured over the entire Q range of the Bragg reflection (e.g., Fig. 2).

Overall, these data suggest that the CoO spins in the biased bilayers prefer a perpendicular orientation relative to the cooling field. However, this alignment could either be a consequence of the Co/CoO interlayer coupling or a direct response to the cooling field. To distinguish between these two effects, we performed field-dependent diffraction measurements on a CoO (40 nm) film. Upon field cooling and measuring the sample in a 2300 Oe field, the ratio of the NSF to SF intensities for the $(1/2\ 1/2\ 1/2)$ reflection is 1.02 ± 0.017 , which is significantly greater than the value measured for the corresponding Co/CoO (40 nm) bilayer (Fig. 3). The random orientation of the AFM spins is unperturbed by cooling fields up to 2300 Oe. The preferred perpendicular orientation observed in Co/CoO bilayers thus appears to result from interlayer coupling. The following measurement for the Co/CoO (40 nm) bilayer further supports this conclusion. We first cooled the sample to 200 K in a 2400 Oe field applied in-plane parallel to the Co growth field direction. We lowered the field to zero and then applied an in-plane field of 500 Oe at an angle of 90° relative to the field cooling direc-

tion while maintaining a temperature of 200 K. The resultant NSF/SF ratio is 1.02 ± 0.011 , which is larger than the 0.873 ± 0.01 ratio obtained in a 2400 Oe field after initially field cooling along the easy axis (Fig. 3). The “frozen” CoO spins thus try to align perpendicular to the reoriented Co layer moment. Since the 500 Oe field is too small to rotate the CoO spins, the moment reorientation is a direct response to the change in the Co magnetization direction.

In conclusion, we observe a preferential orientation of the CoO moments away from the Co magnetization direction in (111) Co/CoO bilayers. Within the (111) growth-axis domain, the perpendicular projection of the CoO moment relative to the field direction is larger than the parallel projection for the three bilayers considered. This result is consistent with Koon’s model,¹⁰ which predicts 90° coupling between the FM and AFM layers. The preferred perpendicular orientation of the AFM develops when the Co/CoO bilayer is field cooled through the AFM T_N into the biased state. Thus the CoO spin reorientation appears to be a direct consequence of exchange coupling between the Co and CoO layers. Unfortunately, we cannot as yet determine if the perpendicular spins reside in the interfacial region, or if the spins in the off-axis {111} domains play an important role. By controlling the AFM spin population in the growth-axis and off-axis domains, future diffraction studies of related CoO films may indeed provide a complete understanding of the physical origin of exchange biasing.

Dependence of exchange field and coercivity on cooling field in NiFe/CoO bilayers

T. Ambrose^{a)} and C. L. Chien

Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

The effects of different cooling fields (H_{FC}) on both the exchange field and coercivity in a NiFe/CoO bilayer have been investigated. The exchange field is strongly effected by H_{FC} at low field values and levels off at high values, whereas the coercivity is only weakly influenced. © 1998 American Institute of Physics. [S0021-8979(98)48411-1]

I. INTRODUCTION

When a ferromagnet/antiferromagnet (FM/AF) bilayer is field cooled across the AF Néel temperature T_N , an exchange coupling is established.¹ As a result, the hysteresis loop at $T < T_N$ is now shifted away from zero field. In addition to this shift, known as the exchange field (H_E), the coercivity (H_C) also increases. The exchange coupling disappears as the bilayer is brought above T_N of the AF layer. It is thought that the magnetic field applied to the FM/AF bilayer during field cooling plays an important role in establishing a strong unidirectional anisotropy due to the exchange coupling. Since the FM layer already orders at $T > T_N$, some form of exchange coupling will result even without cooling in an external field. For example, previous work in FeMn/NiFe bilayers, with the deposition of the AF layer on top of a magnetized FM layer, has shown a displaced hysteresis loop without the necessity of field cooling.² The values of both H_E and H_C , however, are less for the bilayer films without field cooling as compared to those of the field cooled bilayers. In the NiFe/NiO system, the as-deposited samples showed a shifted hysteresis loop at room temperature.³ The values of H_E and H_C at room temperature in fact decreased after the samples were field cooled through the $T_N = 525$ K of NiO. However, heating the sample at elevated temperatures might have degraded the NiFe/NiO interface resulting in lesser exchange coupling values.

It should be also noted that during the fabrication of the FM/AF bilayers, an *in situ* magnetic field in the deposition chamber is often used. In such cases, the as-prepared bilayers have already experienced field cooling. For *ex situ* field cooling, large cooling fields, 10 kOe or more are typically used.¹⁻⁵ There have been no systematic studies of the effects of the value of the cooling field.

In this work, we investigate the importance of the cooling field in the exchange coupling of NiFe/CoO bilayers. The magnitude of the cooling field H_{FC} , has a significant effect on the resultant exchange coupling. The value of H_E increases with H_{FC} before saturation, whereas H_C increases marginally with H_{FC} but decreases slightly at high H_{FC} .

II. EXPERIMENT

For the present studies, a large bilayer sample of 300-Å-thick NiFe (NiFe = Ni₈₁Fe₁₉) was deposited in a field of 200

Oe on top of a [111] oriented CoO layer of 300 Å. The [111] orientation is obtained by growing CoO on a 300 Å Cu buffer layer on a Si [100] substrate. The sample was cut into many squares of a few mm each in size. Every field cooling study was made on a fresh sample at 80 K in either a vibrating sample magnetometer (VSM) or a superconducting quantum interference device (SQUID) magnetometer with a specific cooling field H_{FC} .

III. RESULTS AND DISCUSSIONS

At 298 K, which is above the $T_N = 292$ K of CoO, one obtains a narrow and square hysteresis loop, as shown in Fig. 1(a), with $H_E = 0$ and $H_C = 3$ Oe. Cooling the sample with $H_{FC} = 0$ Oe to 80 K yields a large hysteresis loop with

FIG. 1. Hysteresis curves for the 300 Å NiFe/300 Å CoO bilayer film at (a) room temperature and at (b) 80 K after zero field cooling.

^{a)}Electronic mail: ambrose@huvms.hcf.jhu.edu

FIG. 2. Representative hysteresis loops measured at 80 K of the 300 Å NiFe/300 Å CoO bilayers for cooling field H_{FC} of (a) 5, (b) 20, (c) 100, and (d) 5000 Oe.

$H_C = 129$ Oe as shown in Fig. 1(b), vividly revealing the exchange coupling. Since the bilayer sample was deposited in a field, exchange coupling has been locked in when the sample was cooled in $H_{FC} = 0$. We have purposely placed the sample, so that the deposition field is in the negative H direction of the VSM, such that the loop in Fig. 1(b) is shifted to the right, instead of to the left of $H = 0$.

In Fig. 2 some representative hysteresis loops are shown for various cooling field H_{FC} values. As expected, the loops are now shifted to the left due to H_{FC} . Even a small H_{FC} (e.g., 5 Oe) can shift the loop from the positive side [Fig. 1(b)] to negative side [Fig. 2(a)]. As the value of H_{FC} increases both the shift in the loop (i.e., H_E) and the loop width (i.e., H_C) are observed to increase.

The values of the exchange field H_E and the coercivity H_C are shown in Fig. 3 as a function of the cooling field H_{FC} . The values of H_E and H_C are determined from two fields (H_{left} and H_{right}) of the hysteresis loop where the magnetization is zero by the relations of $H_E = -(H_{left} + H_{right})/2$ and $H_C = -(H_{left} - H_{right})/2$. In this convention a

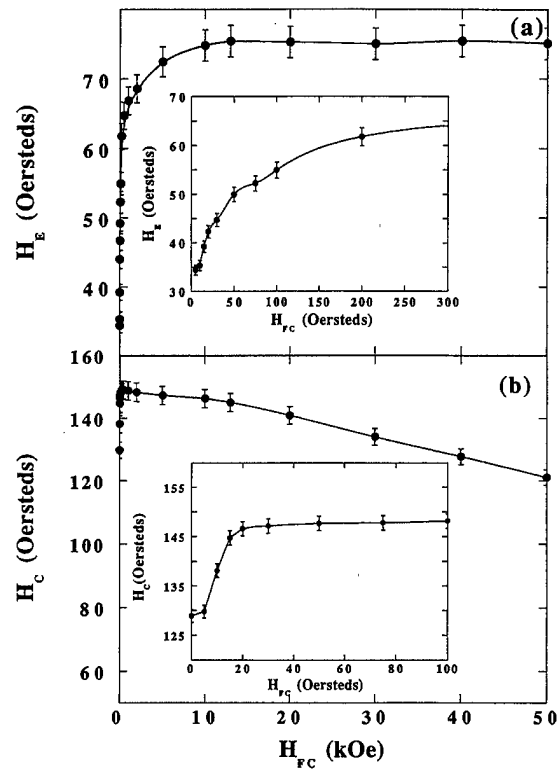

FIG. 3. (a) Exchange field and (b) coercivity at 80 K as a function of the field cooling H_{FC} magnitude. The inset in (a) shows the increase in H_E for small H_{FC} and the inset in (b) shows the increase in H_C for small H_{FC} .

hysteresis loop that is shifted to the left of $H = 0$ is defined as having a positive exchange field and H_C is always positive. As shown in Fig. 3(a), H_E increases monotonically with H_{FC} until it levels off at about $H_{FC} = 8$ kOe. The rapid rise of H_E for small values of H_{FC} is shown in the inset of Fig. 3(a). Beyond $H_{FC} = 10$ kOe, H_E is essentially independent of H_{FC} . For the coercivity H_C , there is a lesser effect due to H_{FC} . The value of H_C rises from 129 Oe at $H_{FC} = 0$ to 142 Oe at $H_{FC} = 20$ Oe and remains essentially unchanged. Only at $H_{FC} = 10$ kOe, H_C begins to decrease slightly to 120 Oe at $H_{FC} = 50$ kOe. One notes that for small H_{FC} (< 100 Oe), the hysteresis loops are not as square as those for larger H_{FC} as shown in Fig. 2. It should be mentioned that every data point in Fig. 3 has been obtained by measuring a fresh and different sample. All of these samples have been cut from a large bilayer. The consistency of the results is remarkable.

In the present case of NiFe/CoO bilayers, even at $H_{FC} = 50$ kOe, the hysteresis loop is always shifted to the left of $H = 0$. In contrast, Fe/FeF₂ bilayers are the only case that the loop can be shifted to the right of $H = 0$ under a very large H_{FC} ,⁴ probably because FeF₂ has a weaker anisotropy as compared to CoO.

It has recently been shown that the FM/AF exchange coupling involves unidirectional (UD) anisotropy and uniaxial (UA) anisotropy, giving rise to H_E and H_C , respectively, both of which are integral parts of the exchange coupling.⁶ The results in Fig. 3 show that the UA anisotropy and H_C are weakly effected by the cooling field H_{FC} . The value of H_{FC} exerts the most influence on the UD anisotropy and H_E , particularly at small H_{FC} values.

Although uncoupled NiFe has a small H_C as shown in Fig. 1(a), the zero field cooled exchange-coupled NiFe at 80 K shown in Fig. 1(b), has much larger H_C value of about 130 Oe. During field cooling, the cooling field H_{FC} must be larger than 130 Oe to maintain the single domain state of NiFe. With H_{FC} less than 130 Oe, the values of H_E will be compromised. Indeed, the field range of $0 < H_{FC} < 130$ Oe causes the most changes in H_E . At $H_{FC} = 300$ Oe, H_E essentially reaches the terminal value. Once NiFe is aligned in the single domain state by a sufficiently large H_{FC} , any further effects on the FM magnetization and the AF spin structure are minimal.

The results shown in Fig. 3 have been taken at 80 K. Since both H_C and H_E have distinct temperature dependencies, we comment on the effect due to measurements at different temperature. Using the film geometry of FM layer on top of the AF layer, H_E saturates to a value at temperatures sufficiently below T_N while H_C increases linearly with decreasing temperature.⁷ If the measurement had been taken at a temperature lower than 80 K, the value of H_C increases but the value of H_E remains unchanged. Both the zero field cooled and the field cooled samples will have a larger H_C at temperatures below 80 K. The results shown in Fig. 3 will be somewhat modified to reflect the lower measuring temperature. A larger cooling field is also required to achieve the ultimate value of H_E because the zero field cooled bilayer has a larger coercivity.

Finally, in NiFe/CoO bilayers, the exchange coupling causes a shifted hysteresis loop and a very large enhancement of the coercivity by about 50 times. Both H_E and H_C are tell-tale signs of exchange coupling. As shown in this work, while the value of H_E can be varied to a large extent, the value of H_C remains essentially unchanged.

IV. CONCLUSION

In conclusion, the magnitude of the cooling field in establishing FM/AF exchange coupling has a strong influence on the value of the resultant exchange field H_E , whereas the coercivity H_C is much less effected. A cooling field in excess of the coercivity of the zero field cooled exchange-coupled FM layer is required in order to reach the ultimate value of H_E .

First-principles exchange interactions between ferromagnetic and antiferromagnetic films: Co on NiMn, a case study

T. C. Schulthess^{a)} and W. H. Butler

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6114

Heisenberg exchange parameters at the interface of antiferromagnetic NiMn with ferromagnetic Co are calculated from first principles. We use a layer version of the Korringa-Kohn-Rostocker multiple-scattering approach and an expression, which is based on the expansion of the band energy, to calculate the exchange parameters from the underlying electronic structure. For bulk systems, the parameter sets yield Curie temperatures that are in good agreement with experimental values. In the interface region, the interlayer interactions in NiMn change significantly compared to the bulk while the intralayer interactions are almost unchanged. © 1998 American Institute of Physics.

[S0021-8979(98)48511-6]

I. INTRODUCTION

Exchange interactions between ferromagnetic and antiferromagnetic films are of considerable interest since their understanding is closely related to the effect known as exchange anisotropy (or exchange bias). Even though this effect has been known since the late 1950s¹ and has important technological applications, its understanding from a microscopic point of view is not established. A simple model that postulates exchange interactions between the antiferromagnet (AF) and the ferromagnet (FM) was introduced by Mauri *et al.*² and explains the effect by a domain wall which is pushed into the AF when the magnetization in the FM is reversed. Malozemoff³ explained the exchange interaction with a random field that is attributed to the interface roughness. However experiments by Nogués *et al.*⁴ showed that exchange anisotropy for Fe/FeF₂ is present with perfectly smooth interfaces and that the roughness actually reduces the bias field. Recently Koon⁵ used a Heisenberg model with nearest neighbor interactions to show that frustration effects near the interface favor the FM to orient perpendicular to the easy axis of the AF. In order to explain exchange anisotropy, the moments have to be confined to the plane parallel to the interface and there is no apparent physical justifications for this restriction.⁶ The major unknowns in the model are the exchange interactions between the AF and the FM. It is the purpose this work to provide such a set of exchange parameters for an AF-FM system which should yield exchange anisotropy. If for example the AF-FM exchange interactions are very large compared to corresponding quantities in the AF, one could expect the net moment induced in the AF layer next to the interface to be large enough such that in-plane motion of the moments is forced by the magnetostatic interactions.

In the present work we follow an approach proposed by Liechtenstein *et al.*⁷ in which Heisenberg exchange parameters can be determined directly from first principles electronic structure calculations. The system that we investigate is chosen to give the best compromise between relevance to

real applications and the possibilities of state of the art electronic structure methods. Usually Ni-Fe is used as a FM on AF NiMn substrates.⁸ In order to simplify the calculations we replace the random Ni-Fe alloy by a pure FM. Since no FM fits naturally onto NiMn we chose Co because it has magnetic properties which are fairly robust with respect to structural distortions and can thus be viewed as a good representative of a FM material to interface with NiMn.

II. METHOD

Our aim is to map the rather complex spin dependent part of the energy functional of density functional theory within the local density approximation onto a simple Heisenberg Hamiltonian,

$$E = - \sum_{ij, i \neq j} J_{ij} \hat{\mathbf{s}}_i \cdot \hat{\mathbf{s}}_j, \quad (1)$$

which is the sum over all exchange interaction, J_{ij} , between moments of fixed magnitude, located on sites labeled by i and represented by a vector of unit length $\hat{\mathbf{s}}_i$. For the description of the electronic structure, multiple scattering theory (MST) provides a natural starting point, since it expands the Green function in a localized basis around every site. The key operator used in this context is the scattering-path operator (SPO), $[\tau_{ij}(\epsilon)]_{Ls, L's'}$, from which the one-particle Green function and hence the charge and moment density may be calculated. It gives, at energy ϵ , the scattered spherical wave of angular momentum $L' = (l', m')$ and spin s' from site j resulting from an incident wave of angular momentum L and spin s at site i . An expression for the exchange parameters in terms of these SPOs, which is based on an expansion of the band energy, was first given for the ferromagnetic case by Liechtenstein *et al.*,⁷ and later extended to the case of arbitrary orientation of the atomic moments by Antropov *et al.*⁹ who wrote the pair exchange parameter as

$$[J_{ij}]_{\alpha\beta} = - \frac{1}{4\pi} \text{Im} \int_{-\infty}^{\epsilon_F} \text{Tr}_L (\Delta_i \tau_{ij}^\alpha \Delta_j \tau_{ji}^\beta - \Delta_i \tau_{ij}^0 \Delta_j \tau_{ji}^0) d\epsilon. \quad (2)$$

^{a)}Electronic mail: schulth@mst.ms.ornl.gov

In this expression $\Delta_i = 1/2 \sum_{\nu=1,3} \text{Tr}_s(t_i^{-1} \sigma^\nu)$ and $\tau_{ij}^\nu = 1/2 \text{Tr}_s(\tau_{ij} \sigma^\nu)$ where t_i is the single site scattering matrix, σ^0 is the 2×2 unit matrix, and $\sigma^{\nu=1,3}$ are the three Pauli matrices. In the present case we will be concerned with collinear ferro and antiferromagnetically aligned atomic moments which we take to be parallel to the z axis.¹⁰ Thus the exchange interactions reduce to

$$J_{ij} = -\frac{1}{4\pi} \text{Im} \int_{-\infty}^{\epsilon_F} \text{Tr}_L(\tilde{\Delta}_i \tau_{ij}^\dagger \tilde{\Delta}_j \tau_{ji}^\dagger) d\epsilon, \quad (3)$$

with $\tilde{\Delta}_i = (t_{i\uparrow}^{-1} - t_{i\downarrow}^{-1}) \text{sgn}(\hat{\mathbf{z}} \cdot \hat{\mathbf{s}}_i)$, and (\uparrow, \downarrow) denote the actual spin channel. There exists an important sum rule,^{7,9} which for collinear spins can be written as

$$J_i = \sum_{j \neq i} J_{ij} \text{sgn}(\hat{\mathbf{s}}_i \cdot \hat{\mathbf{s}}_j) = -\frac{1}{4\pi} \text{Im} \int_{-\infty}^{\epsilon_F} \text{Tr}_L(\tilde{\Delta}_i [\tau_{ii}^\dagger - \tau_{ii}^\dagger] + \tilde{\Delta}_i \tau_{ii}^\dagger \tilde{\Delta}_i \tau_{ii}^\dagger) d\epsilon. \quad (4)$$

This last expression will be used to check the convergence of the calculated exchange interactions.

In order to comply with the symmetry requirement in thin films and planar interfaces, we consider the solid as a superposition of 2D-periodic atomic layers. We use the layer version of the Korring-Kohn-Rostocker (LKRR) method¹¹ to calculate the electronic structure and the approach outlined in Ref. 12 to determine the SPOs that enter the application of Eq. (3) to the layered geometry. The potentials are treated in the atomic sphere approximation (ASA).

III. RESULTS

NiMn crystallizes in a face centered tetragonal structure in which Ni and Mn-layers alternate in the (001) direction. Our calculations¹³ are performed at the experimental lattice constant for thin films,⁸ $a = 3.697 \text{ \AA}$ with a c/a ratio of 0.9573. In accordance with the experimental magnetic structure,¹⁴ we find Ni to be nonmagnetic and the Mn layers to consist of two square sublattices that have opposite magnetic moments. The magnitude of the Mn moment is $3.2 \mu_{\text{Bohr}}$, which is slightly smaller than the experimental value of $3.8 \pm 0.3 \mu_{\text{Bohr}}$. The crystal structure of Co is assumed to match that of NiMn, i.e., it is fct with the same basal lattice constant as NiMn but with a c/a ratio chosen to conserve the experimental atomic volume of hexagonal Co. This approximation is imposed by the requirement of the LKRR method that there has to be an overall 2D periodicity of the system under consideration. However, the robustness of the magnetic structure of Co with respect to changes in the crystal structure allows us to assume that this structural approximation will not significantly alter the magnetic properties of the Co film and the exchange parameters between the NiMn and Co. The magnetic moment of Co in this artificial fct structure is $1.60 \mu_{\text{Bohr}}$ which is similar to $1.63 \mu_{\text{Bohr}}$, the value calculated for hcp Co.

In Table I the exchange interactions of bulk Co and NiMn are compiled. The cutoff is chosen in order that the agreement between the sum over calculated J_{ij} and the value determined directly from Eq. (4) is better than one percent. The results clearly indicate that in Co not only the magnitude

TABLE I. Calculated values for J_i (first row) and J_{ij} (remaining rows) in meV for bulk Co and MnNi. Values for Co are given for the fct and the fcc structure.

but also the coupling between the magnetic moments on different sites are robust with respect to the change of the structure. The Curie temperature that corresponds to the set of exchange interactions can be estimated within a mean field consideration from⁷ $T_C = 2/(3k_B) J_i$ and is found to be 1375 K for fcc Co, which is in good agreement with the experimental value of 1388 K. Similarly, the Neel temperature of NiMn is estimated to 1187 K which is slightly higher than the experimental value of 1070 ± 40 K given by Pál *et al.*¹⁴ Note that the nearest neighbor Mn interactions are remarkably large.

Since not very much is known about the details of the interface between NiMn and a ferromagnetic material, we consider the two possibilities of perfect interfaces, i.e., the cases where Co is next to Ni and Mn, respectively. In the calculations the electronic charge was relaxed self-consistently in 12 atomic layers consisting of 6 Co layers and three repeat units of NiMn. On the AF side of the interface the potentials were fixed to the bulk values and on the other side we used potentials that were converged for Co with the Fermi energy fixed to the value of NiMn. This assures that the electrochemical potential is the same on both side of the interface. We have explicitly checked the effect of this shift in the Fermi energy on the magnetic moments and the exchange interaction in Co and found that it is negligible. The relative size of the atomic spheres of Ni and Mn was chosen such that in the bulk every site is charge neutral.

Even though the method applied here is not limited to the case of collinear atomic moments, the magnetization in Co is chosen to be aligned with the moments of one of the two Mn sublattices. This particular (but arbitrary) choice of the relative magnetization directions provides an important check of the transferability of the exchange parameters. Breaking the symmetry by introducing the NiMn-Co interface with collinear magnetic moments introduces two types of Co-Mn interactions which are equivalent from a geometrical point of view but inequivalent with respect to the relative directions of the moments. The difference between the two gives an estimate of the error introduced when one assumes that the exchange interactions are scalars instead of tensors as actually required by Eq. (2). The results for the exchange interactions of the two types of interfaces are given in Fig. 1. Only values that differ from the corresponding bulk values are shown. Whenever the values between the two sub-

FIG. 1. Exchange interaction in meV for Co-MnNi (left panel) and Co-NiMn (right panel). Squares, circles, up and down triangles represent respectively, Co, Ni, up and down Mn.

sets mentioned previously differ, they are both shown, and it can be seen that the agreement between the sets is reasonable.

All interactions converge rapidly to their bulk values inside Co, but convergence is much slower on the NiMn side. Despite this interface effect on NiMn, the intralayer interactions remain similar to their bulk values. The most significant influence of the interface is between next nearest out of plane Mn neighbors, where the interactions reverse sign and further enforce the antiferromagnetic alignment of the moments. The values for nearest out of plane neighbors are reduced by about 30% but remain strong. In the case where Co layers border with Mn, the Co-Mn coupling between next nearest neighbors is almost the same as between corresponding Mn sites and consequently one order of magnitude larger than the equivalent interactions in Co. The interactions between nearest Co-Mn neighbors however roughly correspond to the average value between the interactions in Co and NiMn. For the other interface, where Ni is next to Co, the coupling between Co and Mn is much smaller, but the Ni layer at the interface has a nonvanishing moment of $0.30 \mu_{\text{Bohr}}$ which leads to finite interactions between Ni and its nearest Co and Mn neighbors.

IV. CONCLUSIONS

The electronic structure and the exchange interactions obtained in the present calculations yield magnetic moments

and critical temperatures that are in good agreement with experimental values. While the Co-Mn interactions at the interface are much larger than the averaged bulk values, they are still smaller than the intralayer interactions in NiMn, which are found to be very large. Since the latter are an intrinsic property of the AF system, we do not expect any qualitative changes in the ratio of interfacial AF-FM and bulk AF-AF interactions for other FM interfaced with NiMn. Thus, following the argumentation mentioned in the introduction, we are lead to the conclusion¹⁵ that a Heisenberg model with perfect interfaces will not yield exchange anisotropy for the NiMn-FM system and therefore more realistic interface structures have to be considered.

Local and global demagnetization process: Is there any self-organized critical behavior?

O. A. Chubykalo and J. M. González

Instituto de Ciencia de Materiales de Madrid, CSIC, Cantoblanco, 28049 Madrid, Spain

The behavior of local and global demagnetization processes (avalanches and Barkhausen jumps) is analyzed in terms of a micromagnetic model. Our study of the statistics of these events as a function of exchange correlation length parameter, system size, and system driving rate shows the absence of self-organized critical behavior if a realistic model of a magnetic system is considered. © 1998 American Institute of Physics. [S0021-8979(98)34011-6]

Systems exhibiting self-organized critical (SOC) behavior react to an external perturbation through collective events (avalanches) having size and duration distribution functions which are system size scaleable.¹ The concept of SOC has been brought to magnetic systems on the basis of the occurrence of collective events during the demagnetization process. In the magnetic systems context, the basic experimental evidence of the occurrence of SOC-like behavior is considered to be the observation of the $1/f^\alpha$ frequency dependence of the power spectrum of the Barkhausen jumps (BJ)^{2,3} (a BJ is identified with the sudden changes of the magnetization of a specimen under the action of a slowly varying external field). The experiments showing this behavior were carried out by using a wide range of the system driving rates without any further system parameters tuning. Also, from theoretical point of view, it has been shown that even in the one-dimensional (1D) case with a single propagating domain wall, the presence of dipolar interactions can originate a SOC-like behavior.² We should, nevertheless, point up here that the actual observation of SOC in magnetic systems is still an open question. For instance, up to now, there is not agreement in the literature about the concrete frequency dependence of the power spectrum associated to SOC. Moreover, the latest experiments on Barkhausen noise have revealed the absence of the common indications of SOC.⁴ Beside this, it has been proposed that the observed behavior could be the consequence of system sweeping of instabilities rather than of a real SOC dynamic.⁵ Finally, most of the theoretical investigations of the SOC behavior are based on the random-field Ising models^{2,6} and consider an equilibrium-type dynamics which is only valid in the limit of zero temperature and infinitely small field sweeping rate.

To try to clarify the above introduced point, we have performed micromagnetic calculations using a model⁷ system describing a textured polycrystal with exchange coupled grains. Our model is of the 1D-type (a chain of magnetic moments, representing atomic planes, and allowed to oriented in 3D). The model considered explicitly anisotropy,

Zeeman, exchange, and magnetostatic energy contributions. The moments were organized in grains, each one having its own easy axis orientation (the easy axes orientations were distributed in a cone having a 20° apex angle whose axis coincided with the applied demagnetizing field direction). The parameters of the system included intrinsic magnetic properties (the exchange-to-anisotropy ratio, a , and the magnetostatic-to-anisotropy ratio, m), system size parameters (the system size, S , measured in number of grains and the grain size, N_1 , measured in number of moments), and driving rate parameters (the field increment Δh , and the duration of the relaxation stage at constant field, ΔMCS , measured in number of Monte Carlo steps). We have considered three models having different intergranular exchange characteristics: (A) ferromagnetic-type interactions with an effective intergranular exchange constant equal to that considered inside each grain, (B) ferromagnetic-type interactions with uniformly distributed effective intergranular exchange couplings, and (C) both ferro- and antiferromagnetic-type coupling with uniformly distributed intensities. The three models differ by the strengths of the coupling between the propagating domain walls and the grain boundaries which act as pinning centers: the pinning is weaker in the model A case and stronger in that of model C. The evolution of the system was followed by using a Monte Carlo algorithm at constant temperature. The dynamics of the magnetic moments was much more realistic than that used in the Ising models. It reproduced adequately real magnetic materials properties: the occurrence of multiple metastable states, the coexistence of temperature- and field-induced nucleation events, the observation of time dependent effects (viscosity), etc. Also, and unlike the Ising-model dynamics, we considered a finite field sweeping rate.

The crucial property of our model is the observation, even for slowly driven systems, of several coexisting propagating domain walls. Thus, we should distinguish between an avalanche (a local event related to the nucleation and consequent propagation, possibly during several field steps,

FIG. 1. Avalanche and BJ size distribution functions for model C. The simulation parameter values are: $a=0.1$, $m=0.3$, $N_1=10$, $S=100$, $\Delta h=0.01$, $\Delta MCS=500$.

of the domain walls limiting a reversed region⁷) and a Barkhausen jump (a global change of the magnetization of the system). Typically, the statistics of these two events are different (see Fig. 1) which is explained by the coexistence of several avalanches in the system. If the avalanche size distribution function, $p(L)$, decreases exponentially, the BJ size distribution function, $p^*(L)$, spans a large fraction of the system size. This is a typical situation in models B and C and takes place in model A when the exchange parameter is small enough (see Fig. 10 of Ref. 7). On the contrary, scaleable avalanche size distribution functions are observed (only for the case of model A, see Fig. 12 of Ref. 7), when the avalanches starting at different points of the system cluster in one unique BJ. One of the necessary conditions of the occurrence of SOC is the observation of system-size scaleable avalanche size distribution functions. The multiple nucleation sites and the occurrence of simultaneously propagating domain walls led, in the case of strong pinning centers (models B and C), to avalanche size distribution functions exponentially decreasing and system-size independent (see Fig. 2). In the weak pinning centers case (model A), the avalanche size distributions can be system-size dependent but this happens for small-size systems only (see Fig. 3 and Fig. 8 of Ref. 7). On the contrary, the BJ size distribution func-

FIG. 2. Avalanche size distribution functions for different size systems (model B). The system parameter values are: $a=5$, $m=0.3$, $N_1=3$, $\Delta h=0.01$, $\Delta MCS=500$.

tions are always system-size dependent (see Fig. 4). The increase of the system size leads to the appearance of additional nucleation centers which originate larger BJ's and even a nonmonotonous behavior for sufficiently large system sizes. In this case, by changing the system driving rate, one can again have statistics similar to those characterizing SOC behavior, i.e., having power distribution functions for the BJ sizes. The observation of such behavior has nothing to do with the occurrence of real SOC since in this case BJ's consist of several uncorrelated events (avalanches started in different parts of the system).

It is commonly accepted that, in order to observe the self-organized criticality, the existence of two time scales (rapid avalanches and large intervals between these events) are necessary (see, e.g., Ref. 8). Under these circumstances, the dynamics of the system is close to that of the sandpile and Ising models. In our model, by varying the system driving rate, the avalanche size and BJ size distributions can coincide, but only for very special values of the driving rate parameters which requires very fine tuning. In general, the decrease of the system driving rate does not make our system to behave similarly to a sandpile system due to the properties present in real systems (and absent in the Ising model), such as viscosity. Indeed, the reduction of the field step leads to

FIG. 4. Barkhausen jump size distribution functions for different size systems (model C). The system parameter values are: $a=0.1$, $m=0.3$, $N_1=10$, $\Delta h=0.01$, $\Delta MCS=500$.

FIG. 5. Barkhausen jumps size distributions functions for different driving rates in model B. The system parameter values are: $a=5$, $m=0.3$, $N_1=3$, $S=100$, $\Delta h=0.01$, $\Delta MCS=500$.

the following effects: (i) decrease of the nucleation rate per constant field stage, (ii) increase of the efficiency of the grain boundaries as pinning centers, and (iii) increase of the relaxational effects. The resulting behavior is a complex interplay between all these mechanism and, for instance, in the BJs case (Fig. 5) the field sweeping rate reduction leads to more rapidly decreasing BJ size distribution functions. (Similar effect is observed for the avalanche statistics.)

In the case of the Ising models, domain walls always consist of two magnetic moments. In our case (as in real situations) domain walls have internal structure and interact with grain boundaries. Thus, the important parameter is the ratio between the exchange correlation length (determining the domain wall size) and the structural correlation length of the system (the grain size N_1). In Ref. 7 it has been shown that in the case of model A, by changing this ratio, the system undergoes a transition from subcritical state (small avalanches only) to supercritical (all avalanches of the system size) via the state of critically (avalanches spanning a considerable part of the system size). In model C (strong pinning centers) the influence of the exchange-to-anisotropy param-

eter on the dynamics of the system is different (see Ref. 9). In this case the antiferromagnetically coupled grain boundaries have a very strong associated pinning effect, which is more relevant in the case of narrow walls (small a values). Grain boundaries also act as very effective nucleation centers (in this case the energy required to partially invert the set of moments forming a wall is sufficiently reduced by the antiferromagnetic coupling). Thus, in the case of model C and unlike the case of model A, presented in Ref. 7, the increase of the exchange-to-anisotropy parameter leads to the reduction of average avalanche size. This parameter also changes the BJs statistics. Therefore, in order to observe critical avalanche and BJ distribution functions, the tuning of the correlation exchange length parameter is necessary. The latter excludes the occurrence of SOC.

In conclusion, our micromagnetic calculations with finite temperature and finite field sweeping rate showed the absence of SOC: (i) The criticality of the avalanche size distribution functions is destroyed by the occurrence of simultaneously propagating domain walls. (ii) The observation of scaleable size distributions (in small size systems exclusively) requires the tuning of the exchange correlation length. (iii) The fact that the BJ size distribution shows, without any parameter tuning, scaleable behavior is not an evidence for the occurrence of SOC because, as we have shown, BJs are sum of simultaneously occurring smaller size events which we believe are uncorrelated.

Non-Heisenberg couplings and ferromagnetic instability in a random antiferromagnetic spin-1 chain

R. N. Bhatt

Department of Electrical Engineering, Princeton University, Princeton, New Jersey 08544

Kun Yang^{a)}

Condensed Matter Physics 114-36, California Institute of Technology, Pasadena, California 91125

A random antiferromagnetic spin-1 chain with both Heisenberg and biquadratic nearest neighbor couplings is found to exhibit a novel ferromagnetic-like instability at low energies, if there is competition between the Heisenberg and biquadratic couplings, *even though each individual nearest neighbor coupling is such as to produce a singlet ground state for the isolated pair*. This instability leads to the generation of ferromagnetic couplings, and thus to the formation of weakly coupled large moments at low temperatures. A perturbative calculation (up to 4th order) is performed to investigate whether such a situation is physically realizable in spin-1 systems. © 1998 American Institute of Physics. [S0021-8979(98)25111-5]

Great interest in quantum spin chains was triggered by Haldane's famous conjecture¹ that integer and half integer Heisenberg antiferromagnetic (AF) chains have qualitatively different behavior. Recently, there has also been much work on random spin chains,²⁻⁷ and considerable progress has been made.

In the past, most theoretical studies of magnetic systems have focused on the Heisenberg model, when the system is isotropic or invariant under spin rotation:

$$H = \sum_{ij} H_{ij} = \sum_{ij} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j, \quad (1)$$

where \mathbf{S}_i is the spin operator on site i , and J_{ij} is the coupling between sites i and j . The coupling is ferromagnetic (F) when $J_{ij} < 0$, and AF otherwise. In the case of spin-one-half system ($S = 1/2$), rotational invariance uniquely constrains the coupling to be of the Heisenberg form (1). In systems with higher spins ($S \geq 1$), however, one may have higher order couplings between spins, and the most general form of the coupling between spins i and j that respects rotational invariance is

$$H_{ij} = \sum_{n=1}^{2S} J_{ij,n} (\mathbf{S}_i \cdot \mathbf{S}_j)^n. \quad (2)$$

It is known that the existence of higher order couplings between spins may change the physics of the system dramatically. For example, in a uniform spin-1 chain with nearest neighbor couplings only ($J_{i,i+1;1} = J$, $J_{i,i+1;2} = D$ and all others zero), besides the usual ferromagnetic phase and the Haldane gapped phase,¹ represented by the ferromagnetic and antiferromagnetic Heisenberg models respectively, the system also supports a spontaneously dimerized phase⁸ and a disordered gapless phase⁹ when biquadratic couplings (D) between neighboring spins are sizable; for special ratios between these couplings, the system is critical and becomes exactly soluble.

When both Heisenberg and biquadratic couplings are present, in principle they may be of opposite nature, i.e., one being AF and favoring a singlet $S_{\text{tot}} = 0$ ground state, and the other being ferromagnetic, favoring a $S_{\text{tot}} = 2$ ground state. In a pure spin-1 chain, the ground state is a singlet as long as the ground state of an individual bond is not the quintuplet (i.e., $S_{\text{tot}} = 2$), and the ferromagnetic tendency (if present) is overwhelmed by AF couplings; thus, no large moments can form. The situation, however, becomes qualitatively different in the presence of *strong randomness*. In this case a powerful method to study the problem is an asymptotically exact real space renormalization group (RG) scheme,² using which we find effective *ferromagnetic* couplings get generated at low energies even if all original couplings are AF overall (i.e., such that the ground state of every nearest neighbor pair taken in isolation is a singlet). A detailed analysis of this effect will be given in a separate publication;¹⁰ however, the basic physical picture is quite simple and summarized below.

In the presence of strong randomness, the energy scales (given by the couplings) become well separated, and low- and high-energy subspaces of the entire Hilbert space get decoupled perturbatively. An efficient way to study the low-energy physics of the system is to focus on the low-energy subspace and perturbatively project the original couplings into this subspace; in this projection process the couplings get renormalized. Due to the different nature of the Heisenberg and biquadratic couplings, they are renormalized by different amounts. In particular, if originally the net coupling is overall AF, after renormalization, the dominant (AF) coupling may get suppressed and a small ferromagnetic coupling (if present) can become dominant, leading to *effective* ferromagnetic bonds.

As an example, we consider a pure AF Heisenberg spin-1 chain, and replace some bonds by very weak impurity bonds (weak compared to the bulk Haldane gap) with both Heisenberg and biquadratic couplings. Consider a bond of this type between spins labeled i and j (Figure 1 shows two such pairs $i, j : 1, 2$ and $3, 4$), with the net coupling $H_{ij} = J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j + D_{ij} (\mathbf{S}_i \cdot \mathbf{S}_j)^2$. In this case, the original pure

^{a)}Electronic mail: kunyang@cco.caltech.edu

FIG. 1. Illustration of effective spin-1/2 edge spins (thick arrows) appearing at the edges of a segment with regular coupling (solid lines). The thick arrows are original spin-1's and thin arrows are effective edge spin-1/2's. The solid lines are original pure Heisenberg couplings; the dotted lines are the original impurity bonds; the dashed (dot-dashed) lines are effective couplings between spin-1/2's of different (same) segment, which are random and can be either F or AF.

chain is chopped into weakly coupled segments of the AF Heisenberg spin-1 chain, and the low-energy degrees of freedom (below the bulk Haldane gap) are due to spin-1/2's (s_i) living at the ends of the segments (see Fig. 1).⁷ The impurity bond between i and j (where i, j could be 1, 2 or 3, 4) couples the two spin-1/2s living on sites i and j (now labeled as i' and j' , and spin operators with lower case, because of the change of spin from spin-1 to spin-1/2), by the Heisenberg form (guaranteed by rotational invariance and special properties of spin-1/2)

$$\tilde{H}_{i'j'} = \tilde{J}_{i'j'} \mathbf{s}_{i'} \cdot \mathbf{s}_{j'} + C_{i'2'}. \quad (3)$$

It is straight forward to show that $\tilde{J}_{i'j'} = \alpha^2 (J_{ij} - D_{ij}/2)$, where α is a projection constant of order 1. Thus the coupling is *ferromagnetic* if

$$J_{ij} - D_{ij}/2 < 0, \quad (4)$$

while the original bond between i and j may be AF under the same condition (i.e., the ground state of H_{ij} is a singlet). The couplings through the Haldane chain may also be either ferromagnetic or antiferromagnetic, as has been discussed earlier.⁷ Thus in the system that we are considering, the low energy effective model is a spin-1/2 chain with random F and AF Heisenberg couplings.

Westerberg *et al.*⁴ have studied the spin-1/2 chain with random F and AF Heisenberg couplings and demonstrated that in such a system at low temperatures active spins form large moments that are weakly coupled. Interesting thermodynamic properties, e.g., a Curie-like susceptibility, follows. Our results here show that such novel behavior can occur in a random spin-1 chain even if all the bare couplings are AF.

In order for the novel effects discussed above to become possible, one needs to have a biquadratic coupling that is of opposite nature to the Heisenberg coupling, with a comparable coupling constant. In the rest of this article we address the issue how non-Heisenberg coupling may be generated in nature and under what conditions they become important, and for convenience focus on systems with $S=1$. If the coupling between two spin-1 objects is rotationally invariant, it must take the form: $H_{ij} = J \mathbf{S}_i \cdot \mathbf{S}_j + D (\mathbf{S}_i \cdot \mathbf{S}_j)^2$, and the biquadratic coupling is ferromagnetic when $D > 0$, and antiferromagnetic otherwise (opposite to the case of Heisenberg coupling J). We model a spin-1 object by putting two spin-1/2 electrons in a open shell with N orbitals of an atom, and

assume Hund's rule coupling forces them to occupy different orbitals and form a total spin-1 (i.e., they have parallel spins).¹¹ We also assume crystal field breaks the degeneracy of the orbitals, and the electrons stay in orbitals 1 and 2 in the ground state; and the energy cost for taking an electron from orbitals 1 or 2 to other orbitals in the same atom without changing its spin is V . This crystal field splitting V , however, may be small compared to the scale of Coulomb interaction U between the electrons (which gives rise to the Hund's rule), and other energy scales involved.

The coupling between two neighboring such spin-1 objects (i and j) comes from hopping of electrons from one site to the other, described by the following hopping Hamiltonian:

$$H' = - \sum_{a,b=1}^N t_{ab} \sum_{\sigma=\uparrow,\downarrow} (c_{ia\sigma}^\dagger c_{jb\sigma} + h.c.), \quad (5)$$

where $c_{ia\sigma}^\dagger$ is the creation operator of an electron in orbital a of site i with spin σ , and t_{ab} is the hopping matrix element which is small compared to the scale of Coulomb interaction U , so the electrons are mostly localized on one site or the other, and the virtual hopping processes give rise to the coupling between the spins. We assume $t_{ab} = t$ for $a=b$, and $t_{ab} = t'$ for $a \neq b$.¹² Since the t_{ab} is spin independent, H' is invariant under spin rotation, and will give rise to rotationally invariant spin couplings. In the following we calculate the strength of such couplings, using standard nondegenerate perturbation theory.

The leading order contribution is of second order in t , which comes from the virtual process where an electron hops from one site to the other, and hops back. We find the energy gain from such processes depends on the total spin of the system:

$$\Delta E_0^{(2)} = - \frac{4t'^2}{U_a} (N-2) - \frac{6(t^2 + t'^2)}{U_a}, \quad (6)$$

$$\Delta E_1^{(2)} = \left[- \frac{4t'^2}{3U_p} - \frac{8t'^2}{3U_a} \right] (N-2) - \frac{4(t^2 + t'^2)}{U_a}, \quad (7)$$

$$\Delta E_2^{(2)} = - \frac{4t'^2}{U_p} (N-2). \quad (8)$$

Here $\Delta E_S^{(2)}$ stands for the energy difference (compared to the unperturbed ground state with $t_{ab}=0$) of states with total spin S to the second order in t ; U_p and U_a are the energy cost for taking one electron from one site to the other, and form a total spin 3/2 (parallel) or 1/2 (antiparallel) with the original spin-1. Hund's rule suggests $U_p < U_a$. We have neglected the crystal field splitting, assuming it is small compared to the U 's.

These spacings between levels with different total spins can be described by a Heisenberg coupling between the two spin-1's with

$$J^{(2)} = \frac{4t'^2}{3} \left(- \frac{N-2}{U_p} + \frac{N-1/2}{U_a} \right) + \frac{2t^2}{U_a}, \quad (9)$$

plus an unimportant constant, and *no* biquadratic coupling, i.e., $D^{(2)}=0$. This is not surprising because second-order processes involve only one electron exchange; since the spin

of the electron is one-half, Heisenberg coupling is the only possibility that respects rotational invariance. Since $J^{(2)}$ involves the difference of terms, it may have either sign: the energy denominator favors parallel spins, while antiparallel spins have greater phase space due to the Pauli principle, and there exists the possibility that the magnitude of $J^{(2)}$ can be small, if the two opposite terms in (9) are close in magnitude.

Biquadratic couplings can arise from higher order hopping or exchange processes, involving hopping of two or more electrons, and will be of order $O(t^4)$ or higher. Naively, one would expect this to be much smaller than J because in most cases the additional t 's lead to additional energy denominators, of order U , will introduce at least two more factors of t/U , which is small. We point out, however, that there is a special class of two-electron hopping processes that can partially avoid the additional factors of $1/U$, and potentially make sizable contribution at order t^4 (which could be comparable to J under favorable circumstances). These are processes where one electron hops from site i to site j , and another electron hops from site j to site i , and in the intermediate state where there are two electrons on each site, the spins arrange themselves to form a triplet on each site. The energy of such an intermediate state is not of the Coulomb energy scale U , but of the crystal field splitting of the orbitals V , which may be quite small. The fourth-order perturbation calculation of the contribution of these processes is quite involved; the results are

$$\Delta E_0^{(4)} = -\frac{2t'^4}{VU_a^2}(N-2)^2, \quad (10)$$

$$\Delta E_1^{(4)} = -\frac{8t'^4}{9V}\left(\frac{1}{U_p} - \frac{1}{U_a}\right)^2(N-2)^2, \quad (11)$$

$$\Delta E_2^{(4)} = -\frac{8t'^4}{VU_p^2}(N-2)^2. \quad (12)$$

From this we obtain the contributions to J and D from the fourth order processes discussed above to be

$$J^{(4)} = -\frac{8t'^4}{9V}\left(\frac{2}{U_p^2} - \frac{1}{U_a^2} + \frac{1}{U_a U_p}\right)(N-2)^2, \quad (13)$$

$$D^{(4)} = -\frac{2t'^4}{9V}\left(\frac{4}{U_p^2} + \frac{1}{U_a^2} - \frac{4}{U_a U_p}\right)(N-2)^2. \quad (14)$$

From the above expressions, we see that the biquadratic coupling D may be comparable to the usual Heisenberg coupling J if (a) V is small,¹³ (b) the orbital degeneracy N is

large, and (c) if there is a cancellation due to opposing terms in Eq. (9). In addition to the factors considered above, some other physical effects not included in our model may also enhance D . One possibility is that the hopping matrix element may depend on the ionic state, e.g., it may be larger for a second particle hop, because of the ion's bigger size. This will further enhance the contribution of the fourth-order term, and therefore the biquadratic coupling.

In summary, we have shown that there exists in a random *antiferromagnetic* spin-1 chain with nearest neighbor isotropic couplings, consisting of both Heisenberg and biquadratic exchange, the possibility of a *ferromagnetic-like* instability. This causes the formation of arbitrarily large effective spins at low temperatures, leading to a pure Curie behavior for the magnetic susceptibility. We have also discussed how non-Heisenberg coupling between spins are generated for $S > 1/2$, and under what conditions they become comparable to the Heisenberg coupling. We argue that these conditions may be realizable in real systems.

¹¹ In some real systems, like, e.g., Ni^{2+} , we have two holes instead of two electrons in the $3d$ shell, but the physics should be the same.

¹² In real systems the hopping matrix element depends on the specific orbitals involved and may be zero for certain pairs of orbitals due to symmetry. To simplify the algebra, we assume it is t for hopping between the same orbitals and t' for different orbitals; these may be taken to be the average values of the two. The results are not altered qualitatively by this simplification.

¹³ In principle, when V is small compared to t , the straightforward nondegenerate perturbation expansion needs to be modified. However, the final answer will be of the same order of magnitude as that obtained from the perturbation calculation.

Universal magnetic fluctuations in the two-dimensional XY model

We discuss the probability distribution function for the magnetic order parameter M , in the low temperature phase of the two-dimensional XY model. In this phase the system is critical over the whole range of temperature. The thermally averaged value of the order parameter $\langle M \rangle$, which is zero in the thermodynamic limit, has abnormally large finite size corrections. An exact result, within a spin wave calculation gives $\langle M \rangle = (1/2N)^{T/8\pi J}$, where J is the magnetic exchange constant and N the number of spins. We show, using Monte Carlo simulation, that the distribution function, $Q(y - \langle y \rangle)$, $y = T^{-1} L^{T/4\pi J} M$, is an asymmetric universal function. Using a diagrammatic technique, we show that the asymmetry comes from three-spin and higher correlations. If only two-spin correlations are considered, the distribution is Gaussian. However, as there are contributions from two-spin terms separated by all distances, the distribution remains broad and is consistent with a divergent susceptibility. © 1998 American Institute of Physics. [S0021-8979(98)51911-1]

The long-ranged correlations that characterize a critical point mean that at this special point finite size effects are much more important than the $1/\sqrt{N}$ corrections given by the central limit theorem.¹ For example scaling arguments give, for the magnetization, $\langle M \rangle$, at a critical point² $\langle M \rangle \sim L^{-\beta/\nu}$, with β and ν the critical exponents for the magnetization and the correlation length. For strong fluctuations β is small and ν is large, leaving the finite size magnetization measurable right into the physical domain. This is nowhere better observed than in the low temperature phase of the two-dimensional XY model, where the system is critical over a whole range of temperature. In fact it is an ideal system in which to study finite size fluctuations near a critical point as it shows critical behavior over a range of temperatures below the Kosterlitz–Thouless transition temperature T_{KT} ,³ it is extremely accessible to analytic techniques and is of broad experimental relevance.⁴

The model is defined with the Hamiltonian

$$H = -J \sum_{\langle i,j \rangle} \cos(\theta_i - \theta_j), \quad (1)$$

where J is the ferromagnetic coupling constant and θ_i the angle of orientation of spin vector S_i , constrained to lie in a plane. The summation is over nearest neighbors and we take the spins to be on the sites of a square lattice with periodic boundary conditions. We use a system of units with Boltzmann's constant k_B equal to unity throughout. We simplify this to what we refer to as the harmonic XY or HXY model.⁵ Its Hamiltonian is

$$H = -J \sum_{\langle i,j \rangle} \left[1 - \frac{1}{2} (\theta_i - \theta_j - 2\pi n)^2 \right], \quad (2)$$

where $n=0, \pm 1$ is an integer chosen so that $(\theta_i - \theta_j - 2\pi n)$ lies between $\pm \pi$. This model is almost the Villain model,⁶ but is more practical from a numerical point of view, as the vortex variable n is not a thermodynamic variable, but is constrained to the values $n=0, \pm 1$.⁷ We concentrate, in this article, on the temperature regime well below T_{KT} where the vortex density is exponentially small and the HXY reduces to a model of harmonic spin waves, which can be solved exactly.⁸

We define an instantaneous scalar order parameter M :

$$M = \frac{1}{N} \sqrt{\left(\sum_{i=1,N} S_i \right) \cdot \left(\sum_{i=1,N} S_i \right)}. \quad (3)$$

Within the spin wave approximation one can derive the following result for the equilibrium magnetization $\langle M \rangle$, exact to leading order in N :⁸

$$\langle M \rangle = \left(\frac{1}{2N} \right)^{T/8\pi J}. \quad (4)$$

$\langle M \rangle$ falls to zero in the thermodynamic limit, which confirms the Mermin–Wagner theorem⁹ that the thermodynamic magnetization is zero at all finite temperature. However, putting in numbers for $T \sim O(J)$ one can easily convince oneself that $\langle M \rangle$ is measurable throughout the physical domain.

The susceptibility per spin, defined as

^{a)}Electronic mail: pcwh@enslapp.ens-lyon.fr

FIG. 1. $\log[\sigma Q(M)]$ vs $(M - \langle M \rangle)/\sigma$ for $T/J=0.5$ for $N=100$ (stars), $N=1024$ (circles), $N=10\,000$ (squares), and for $T/J=1.0$ for $N=1024$ (triangles).

$$\chi = \frac{N}{T} (\langle M^2 \rangle - \langle M \rangle^2), \quad (5)$$

is given by the expression

$$\chi = \frac{\langle M \rangle^2}{T} \sum_r \left\{ \exp \left[\frac{T}{J} \times G(r) \right] - 1 \right\}, \quad (6)$$

where $G(r)$ is the lattice Green's function for a square lattice

$$G(r) = \frac{1}{N} \sum_{q \neq 0} \frac{e^{i\mathbf{q} \cdot \mathbf{r}}}{\gamma_q}, \quad (7)$$

$$\gamma_q = 4 - 2 \cos(q_x) - 2 \cos(q_y).$$

To an excellent approximation one finds

$$\chi = \frac{1}{2a_{2D}} \frac{N \langle M \rangle^2 T}{J^2}, \quad a_{2D} = 258.6, \quad (8)$$

with the susceptibility per spin therefore diverging as $\chi \sim N^{1-T/4\pi J}$.

From Eq. (8) we see that the prefactor of the "divergent" susceptibility is small and goes to zero as T goes to zero. The normalized standard deviation of the distribution,

$$\frac{\sigma}{\langle M \rangle} = \sqrt{\frac{\langle M^2 \rangle - \langle M \rangle^2}{\langle M \rangle^2}} = \frac{\sqrt{N\chi T}}{N \langle M \rangle}, \quad (9)$$

has a numerical value of only ≈ 0.04 T, but is independent of system size. In a noncritical system, with finite correlation length one expects $\sigma/\langle M \rangle$ to go to zero as $N^{-1/2}$ in the large N limit. The scalar magnetization therefore appears to be a well-defined quantity despite its fluctuations, as measured by the susceptibility, being divergent in the thermodynamic limit, as shown above.

We are interested here in the probability distribution function $Q(M)$. The distribution function for the magnetization at a critical point has been discussed by several authors.^{2,10} Binder² argues, using the example of an Ising system with distribution $P_L(M)$, that within the critical region

$$P_L(M) = L^{\beta/\nu} P(L/\xi, ML^{\beta/\nu}), \quad (10)$$

where ξ is the correlation length. ξ is the length scale at which one can expect a cross over to a noncritical regime with Gaussian fluctuations. Very close to the critical point the correlation length of the infinite system would be much bigger than the system size L . In this situation one expects self-similar behavior in the system, with L being the only important scale above the microscopic length. P_L should therefore depend on the single variable $ML^{\beta/\nu}$.

For the two-dimensional XY model, despite the fact that β and ν do not exist in a conventional sense,⁵ their ratio, x , is perfectly well defined through Eq. (4) for all temperatures $T \leq T_{KT}$. Within the spin wave approximation one finds $x = T/4\pi J$. Near T_{KT} the scaling relation

$$x = \beta/\nu = \frac{d}{\delta+1} = \frac{1}{8} \quad (11)$$

is satisfied by putting $T/J \approx \pi/2$, which is the mean field approximation for T_{KT} .³ More precisely, we have shown⁵ that the renormalization of the temperature due to vortices is taken into account correctly by replacing T/J with the effective temperature $(T/J)_{\text{eff}} = \pi/2$ at a temperature $T^*(L) \approx T_{KT}$, in which case the scaling relation is satisfied exactly. We therefore expect universal finite size scaling in the same manner. However, in our case we have a line of critical points for all temperatures less than T_{KT} with temperature dependent exponent x . It is therefore by no means obvious that we should find the same scaling functions for different temperatures.

In Fig. 1 we plot Monte Carlo data for $\log[\sigma Q(M)]$ versus $(M - \langle M \rangle)/\sigma$ for $N=10^2$, 10^3 , and 10^4 spins at $T/J=0.5$ as well as for $N=10^3$ spins at $T/J=1.0$. The run length was typically 10^7 Monte Carlo steps per spin. The data clearly fall on a universal curve over five orders of magnitude. We can effectively define a reduced variable $y = M/\sigma \sim T^{-1} ML^{T/4\pi}$, with $\bar{y} = \langle M \rangle/\sigma \sim T^{-1}$ which is independent of L . Our universal function is therefore of the form $Q(y - \bar{y})$ and we do indeed find a single universal function for all temperatures and all system sizes. We observe corrections to universality for systems containing less than 100 spins.

The function is clearly not Gaussian and shows an asymmetry, with an enhanced probability for fluctuations towards a smaller magnetization. This corresponds to the fact that the long wavelength spin waves, with amplitude diverging with N , provide the possibility of large scale fluctuations below the average value, at zero cost in free energy. Indeed the logarithm of $Q(M)$ corresponds to the effective free energy at the critical point, or fixed point function, discussed in detail during the pioneering days of critical phenomena.¹¹

From a mathematical point of view the spin wave model studied here offers the opportunity to calculate the distribution function analytically. We present here some analytic results as a first step towards the calculation of $Q(M)$.

We consider the moments of the distribution

$$\langle z^n \rangle = \left\langle \left(\frac{M - \langle M \rangle}{\sigma} \right)^n \right\rangle, \quad (12)$$

and are interested, initially in their leading N and T dependence. After some work one can write for $\langle M^n \rangle$ (Ref. 12),

$$\langle M^n \rangle = \left(\frac{\langle M \rangle}{2N} \right)^n \text{Tr} \prod_{i \neq j}^n e^{-\epsilon_i \epsilon_j (T/2J) G(\mathbf{r}_i - \mathbf{r}_j)}, \quad (13)$$

where the trace is over the variables $\epsilon_i = \pm 1$ and over the sites \mathbf{r}_i . For the n th moment the product contains n exponential terms. $G(\mathbf{r}_i - \mathbf{r}_j)$ is the lattice Green's function joining points i and j .

This is the starting point for a diagrammatic expansion: the exponential is expanded and the trace taken. The sites are represented by vertices and the Green's functions $G(\mathbf{r}_i - \mathbf{r}_j)$ by a line joining the points i and j . Numerically we find that the graphs making the leading contribution consist of simply connected single loops. Further, in calculating the moment $\langle z^n \rangle$ we find that the only single loop graphs that count are those of length n . The contribution of such a graph to $\langle M^n \rangle$ is then

$$\frac{1}{n!} \left(\frac{-T\langle M \rangle}{2NJ} \right)^n G(r_{12})G(r_{23})\dots G(r_{n-1n})G(r_{n1}), \quad (14)$$

and passing into Fourier space the graph finally reduces to

$$\left(-\frac{T\langle M \rangle}{2NJ} \right)^n \sum_{\mathbf{q} \neq 0} \frac{1}{\gamma_{\mathbf{q}}^n}. \quad (15)$$

One can see that the leading N dependence of the sum over $\gamma_{\mathbf{q}}^{-n}$ is N^n and we find numerically that higher order corrections disappear rapidly with increasing N . Given that $\sigma \sim T\langle M \rangle$, we therefore find that to an excellent approximation the moments $\langle z^k \rangle$ are independent of N and T , in agreement with our numerical simulations.

Although this result is specific to the Gaussian model we have used, it is interesting to note that it shows, explicitly and without recourse to a scaling hypothesis or to phenomenology of any kind, the existence of a universal non-Gaussian finite size scaling function $\sigma Q((M - \langle M \rangle)/\sigma)$.

Finally, and after some rather tedious manipulation, we are able to write the distribution Q in the form

$$Q(M) = \int_{-\infty}^{\infty} \frac{dt}{2\pi\sigma} \exp -it \left(\frac{M - \langle M \rangle}{\sigma} \right) + \sum_{k \geq 2} \frac{a_k}{2k} \left(-it \sqrt{\frac{2}{a_2}} \right)^k, \quad (16)$$

where

$$a_k = \frac{1}{N^k} \sum_{\mathbf{q} \neq 0} \frac{1}{\gamma_{\mathbf{q}}^k}. \quad (17)$$

From this expression one can see clearly the origin of the non-Gaussian element in the distribution. Including the term $k=2$ only, we find a Gaussian function. This comes explicitly from the sum of contributions from two-vertex loops, or two-particle correlations only. Just keeping these terms, which corresponds to a Hartree approximation, results in a wide distribution with a correctly diverging susceptibility; but the distribution remains Gaussian. The non-Gaussian be-

havior therefore comes from graphs of three and higher order, with the asymmetry coming from the odd terms.

The low temperature, or spin wave region yields itself extremely well to analytical work and to numerical work. At a critical point, in order to enter into the universal regime one must exceed a transient length scale over which microscopic details disappear.¹¹ Within the Gaussian approximation, the transient effects are exceedingly small with the result that the probability distribution fits onto the universal curve with as little as 100 spins.

There is a considerable literature on universal finite size scaling behavior, with Ising systems being predominantly considered.^{13,14} In addition, models similar to ours occur in problems of the growth of interfaces between two phases.¹⁵ We have shown here, in this work that the two-dimensional XY model is an ideal system in which to further the study of critical fluctuations in a finite system.

Our result that the universal function is independent of the critical exponents is not what one would expect in general. Rather, one expects the form of the function to depend on the universality class and hence on the exponents. It will be interesting to try to quantify this universality class dependence in other models, where n -spin correlators are not simple functions of two-spin correlators.

In conclusion we have shown that the critical finite size corrections to the thermodynamic limit spill over into the physical domain. This being the case experiments on a large class of systems should be possible in which order parameter distribution function analogous to $Q(M)$ can be measured directly.

It is a pleasure to thank J. L. Cardy, J. T. Chalker, Z. Rač, and T. Ziman for useful discussions.

On the basis of the relation $T(\sigma, H)$ derived within the framework of the Bean-Rodbell model a semiquantitative analysis of (B, T) magnetic phase diagrams in the hexagonal region of the $\text{MnFeP}_{1-x}\text{As}_x$ ($0.15 \leq x \leq 0.66$) series of compounds was carried out. It was found that the first order transition line in the (B, T) plane is terminated by the isolated critical point for $x=0.33$ and $x=0.5$ contents. The positive value of dB_C/dT and the saturation of the magnetization was found to be in agreement with the experiment. Thus the Bean-Rodbell model and the molecular field approximation can be applied to describe the discontinuous Ferro-Para magnetoelastic phase transition. Semiquantitative agreement between the theoretical and the experimental (B, T) magnetic phase diagrams was obtained. For the $\text{MnFeP}_{0.67}\text{As}_{0.33}$ compound the electronic structure calculations were performed by the Korringa-Kohn-Rostoker with the coherent potential approximation method. The density of states (DOS) curve calculated in the nonmagnetic state shows that the Fermi level falls in a deep minimum of DOS. It indicates that the metamagnetic B -field induced phase transition between the paramagnetic and the ferromagnetic states may be observed (metamagnetism of itinerant electrons) which remains in good agreement with our experimental results. © 1998 American Institute of Physics. [S0021-8979(98)52011-7]

INTRODUCTION

The $\text{MnFeP}_{1-x}\text{As}_x$ series of compounds in the hexagonal region (Fe_2P type) considered in this article exhibit very peculiar magnetic properties. In zero magnetic field, for investigated ranges of temperature and composition, the metamagnetic magnetoelastic phase transition was pointed out.^{1,2} Moreover, the influence of dc magnetic field, pressure, and temperature on magnetoelastic phase transitions of these compounds were also established.¹⁻³ For $0.2 \leq x \leq 0.275$ the (B, T) phase diagrams show the existence of the critical end point while for $x=0.33$ and $x=0.5$ contents the isolated critical point (ICP) was confirmed. For $\text{MnFeP}_{0.67}\text{As}_{0.33}$ and $\text{MnFeP}_{0.5}\text{As}_{0.5}$ the metamagnetic field induced phase transition between the paramagnetic (disordered) state and the ferromagnetic one was observed.^{1,2,4,5} In this article we present a semiquantitative analysis of (B, T) magnetic phase diagrams for $x=0.33$ and $x=0.5$ contents based both on the molecular field approximation (the Bean-Rodbell model⁶) and on the itinerant electron model of phase transitions.⁷⁻⁹ In the latter the ground state density of states (DOS) electronic structure of $\text{MnFeP}_{0.67}\text{As}_{0.33}$ was calculated using the Korringa-Kohn-Rostocker (KKR) with the coherent potential approximation (CPA) method.^{10,11} The spin polarized electronic structure computations were presented for Fe_2P

and $\text{MnFeP}_{0.7}\text{As}_{0.3}$ in an earlier paper.¹² The calculated magnetic moments were found to be in close agreement with diffraction neutron measurements.¹²

RESULTS AND DISCUSSION

The critical behavior of the magnetic system will be analyzed on the basis of the generalized Gibbs free energy in the form as follows:⁶

$$G_j(\sigma, T) = G_{\text{ex}} + G_H + G_{\text{dist}} + G_{\text{entr}} + G_{\text{press}}, \quad (1)$$

where G_{ex} , G_H , G_{dist} , G_{entr} , and G_{press} are the exchange energy calculated on the basis of the molecular field model, the Zeeman energy, the elastic energy, the entropy term, and the pressure term, respectively. Furthermore, the thermodynamical analysis of the (B, T) magnetic phase diagrams will be limited to the diagrams where the ICP was experimentally found. Minimizing the free energy G [Eq. (1)] with respect to volume in the case of lack of external pressure ($G_{\text{press}} = 0$) we obtain

$$\begin{aligned} \frac{G_{\text{min}}}{Nk} = & -\frac{3j}{2(j+1)} T_0 \sigma^2 - \frac{9}{20} \frac{[(2j+1)^4 - 1]}{[2(j+1)]^4} T_0 \eta_j \sigma^4 \\ & - \frac{g \mu_B j H \sigma}{k} - TS_j(\sigma), \end{aligned} \quad (2)$$

where

^{a)}Corresponding author; electronic mail: puzach@cyf-kr.edu.pl

FIG. 1. Calculated magnetization $\sigma_H(T)$ for $\text{MnFeP}_{0.5}\text{As}_{0.5}$ ($j=2$, $\eta=1.62$, $T_0=250$ K).

$$\eta_j = \frac{5}{2} \frac{[4j(j+1)]^2}{[(2j+1)^4 - 1]} Nk\kappa T_0 \beta^2,$$

N is number of magnetic atoms per unit volume; T_0 is the Curie temperature for assuming incompressible lattice; S_j is magnetic entropy, k is the Boltzmann constant; g is the Landé factor; κ is the coefficient of compressibility, and j is total angular momentum.

When minimizing G_{\min} [Eq. (2)] with respect to σ in the presence of external magnetic field, we obtain an implicit expression of temperature T dependent relative magnetization σ :

$$T(\sigma, H) = \frac{\left[aT_0\sigma + bT_0\sigma^3 + \frac{g\mu_B j}{k} H \right]}{B_j^{-1}(\sigma)}, \quad (3)$$

where

$$a = \frac{3j}{j+1}; \quad b = \frac{9}{5} \frac{(2j+1)^4 - 1}{[2(j+1)]^4} \eta_j; \quad B_j^{-1}(\sigma) = \frac{\partial S_j}{\partial \sigma}.$$

From Eq. (3) the magnetization plots at constant magnetic field can be derived from the isofield magnetization $\sigma_H(T)$ curves.

The magnetization measurements in the low temperature range show that the saturation magnetization is about $\sim 4 \mu_B/\text{fu}$ so we conclude that the angular momentum is $j=2$ (it was assumed that $g=2$). Also, the magnetic moment of $3.9 \mu_B/\text{fu}$ was found from the KKR-CPA calculations. In the external magnetic field up to 28 T the ICP was unambiguously experimentally confirmed only in the case of two As contents. So the samples $\text{MnFeP}_{0.5}\text{As}_{0.5}$ and $\text{MnFeP}_{0.67}\text{As}_{0.33}$ were chosen for detailed numerical analysis. The magnetization versus temperature plots $\sigma_H(T)$ for selected external magnetic field values are presented in Fig. 1. They were obtained using the following model parameters: $j=2$, $\eta=1.62$, and $T_0=250$ K. In this case the best agreement with the experimental results measured in $\text{MnFeP}_{0.5}\text{As}_{0.5}$ was achieved.⁴ In the magnetic fields $B=0$ and 5 T the first order transition still exist (lines 1 and 2 in Fig. 1). However, for the fields $B=10$ and 12 T the first

order transition is not shown. It means that the first order discontinuous phase transition is terminated above $B \sim 10$ T. It allows one to conclude, that in the vicinity of $T_{\text{cr}} \sim 300$ K and $B_{\text{cr}} \sim 11$ T, the ICP is reached. Such a phenomenon was experimentally observed for $\text{MnFeP}_{0.5}\text{As}_{0.5}$.^{1,4} Similar dependencies of magnetization versus temperature $\sigma_H(T)$ at selected magnetic fields for $\text{MnFeP}_{0.67}\text{As}_{0.33}$ were also calculated. For magnetic field $B=0$, 10, and 20 T the discontinuous phase transition occurs. However, for field $B \sim 25$ T this type of transition is not found. It is concluded that in the vicinity of $T_{\text{cr}} \sim 250$ K and $B_{\text{cr}} \sim 25$ T the ICP is established. In the case of this compound ($x=0.33$) the best agreement with experimental results was obtained for $j=2$, $\eta=2.7$, and $T_0=155$ K.

It is interesting to examine the free energy in more detail. Let us return to the minimal Gibbs free energy expressed by Eq. (2). We expand the entropy into a power series of σ and after collecting terms in like powers of σ the $(G_{\min} - G_0)/Nk$ can be written as follows:⁴

$$\begin{aligned} \frac{G_{\min} - G_0}{Nk} = & \left(\frac{3j}{j+1} \right) [T - T_0] \frac{\sigma^2}{2} + \frac{9}{5} \frac{[(2j+1)^4 - 1]}{[2(j+1)]^4} \\ & \times (T - \eta_j T_0) \frac{\sigma^4}{4} + 6c_j T \frac{\sigma^6}{6} - \frac{g\mu_B j H}{k} \sigma. \end{aligned} \quad (4)$$

The coefficient c_j of the magnetic entropy term can be calculated on the basis of the power series expansion of the magnetic entropy expression into powers of σ (up to sixth order). Thus c_j is determined as

$$c_j = \frac{1}{2} \frac{j}{(j+1)^5} \left(\frac{99}{175} j^4 + \frac{198}{175} j^3 + \frac{63}{50} j^2 + \frac{243}{350} j + \frac{243}{1400} \right). \quad (5)$$

To illustrate some features of the free energy at the first order transition, the free energy isotherms in the vicinity of the temperature corresponding to ICP are reported in Fig. 2. For this the model parameters $j=2$, $\eta=1.62$, $T_0=250$ K,

FIG. 2. The free energy $(G_{\min} - G_0)/Nk$ isotherms vs σ in the vicinity of the ICP as calculated on the basis of Landau expansion [Eq. (4)] for $j=2$; $\eta=1.62$; $T_0=250$ K and $B=10$ T. (1) $T=330$, (2) 320, (3) 314, (4) 313, (5) 310, (6) 305, and (7) 300 K.

FIG. 3. Total DOS for $\text{MnFeP}_{0.67}\text{As}_{0.33}$ in the nonmagnetic ground state. The inset shows the DOS in the vicinity of E_F .

and $B = 10$ T were chosen for calculations of $(G_{\min} - G_0)/Nk$. The free energy minima which determine the spontaneous magnetization were found to be strongly dependent on temperature. The free energy minima ($B = 10$ T) become less and less pronounced and shift towards higher values of σ when the temperature decreases.

Now we will discuss the itinerant electron paramagnetism, which was observed in several 3d-metal compounds [i.e., YCo_2 , TiBe_2 , FePt_3 , $\text{Co}(\text{Se}_{1-x}\text{S}_x)_2$, RCO_5]⁷ under magnetic fields in the range 10–50 T where different types of transitions either from paramagnetism to ferromagnetism or from antiferromagnetism to ferromagnetism were observed. This first order type of transition, characteristic of itinerant paramagnets in the magnetic field, is strongly related to a shape of the density of states near the Fermi level. The magnetic properties of paramagnets with the DOS close to the Stoner criterion may be significantly modified by magnetic field if the DOS strongly varies in the vicinity of E_F .^{8,9}

In Fig. 3 the total DOS curve for $\text{MnFeP}_{0.67}\text{As}_{0.33}$ in the nonmagnetic state is presented. A more detailed analysis of the DOS curve near the Fermi level showed that E_F is located in the vicinity of the deep DOS minimum (Fig. 3). The semiquantitative computations of the DOS derivative in the neighborhood of the Fermi energy demonstrate that the second derivative of DOS calculated at E_F for $\text{MnFeP}_{0.67}\text{As}_{0.33}$ is positive. We conclude that the field induced metamagnetic transition from the paramagnetic (nonmagnetic in KKR-CPA computations) to the magnetically ordered phase is explained theoretically in this compound, in agreement with the experiment. A specific manifestation of the itinerant nature of the metamagnetic transition is the strong field dependence of the susceptibility of the paramagnet. This property was experimentally observed in the case of $\text{MnFeP}_{0.67}\text{As}_{0.33}$ and

$\text{MnFeP}_{0.5}\text{As}_{0.5}$.^{1,2,4} Quantitative analysis of such a type of phase transition is possible if the temperature dependence of the molecular field coefficient λ is known. Note that for Fe λ strongly depends on the temperature but for Mn this dependence was not found.⁹

As a comparison, the electronic band structure calculations for Fe_2P in the paramagnetic (nonmagnetic) state were performed by KKR method, which showed a very profound minimum of the density of states in the vicinity of the Fermi level. The Fermi energy E_F is in the region where the first derivative of the density of states is very large. This is in agreement with the strong sensitivity of the magnetic properties of Fe_2P on such parameters as external pressure, magnetic field, and composition. Moreover, the second derivative of the DOS curve calculated at the Fermi level is also positive. Note that an isolated critical point, similar to that in the $\text{MnFeP}_{1-x}\text{As}_x$ series, was found experimentally in this compound. However, in the latter the value of the critical field was found to be much smaller than that in the former.¹³

CONCLUSIONS

Semiquantitative analysis of magnetic phase diagrams exhibiting the ICP for the $\text{MnFeP}_{1-x}\text{As}_x$ series of compounds led to conclusions that can be summed up as follows.

- (1) The Bean–Rodbell model was successfully applied to describe the discontinuous Ferro–Para magnetoelastic phase transition.
- (2) A semiquantitative agreement between the theoretical and the experimental (B, T) magnetic phase diagrams was obtained. The discontinuous transition line in the (B, T) plane is terminated by the ICP.
- (3) For the nonmagnetic $\text{MnFeP}_{0.67}\text{As}_{0.33}$ compound KKR–CPA ground state electronic structure calculations were performed. They showed that the Fermi level is in the vicinity of the deep minimum of the DOS curve.

Magnetic behavior of the low-dimensional compounds $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ and $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$

D. Eckert, K. Ruck, M. Wolf, G. Krabbes, and K.-H. Müller^{a)}

IFW Dresden, P.O. Box 270016, 01171 Dresden, Germany

Orthorhombic $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ contains folded Cu_2O_4 chains along the crystallographic a direction with two different Cu sites. In single crystals of this compound the magnetization measured for a field applied parallel to the a axis shows a spin-flop transition at a threshold field of 2.6 T for temperatures below $T_N \approx 20$ K. Above T_N a Curie–Weiss behavior is found with a paramagnetic moment of $2.0 \mu_B$ per Cu atom. Parallel to the b or c axis the magnetization increases linearly with the field strength, and no metamagnetic transition was detected for these directions. It is concluded that $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ has localized magnetic moments which, at low temperatures, order antiferromagnetically parallel to the a axis. The bulklike magnetic behavior of this compound is probably caused by a strong coupling between the Cu_2O_4 chains. Tetragonal $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ is built up of Cu_3O_4 planes, also with two types of copper atoms (Cu_A, Cu_B). Its magnetization increases nearly linearly with the field. Below $T_{NA} = 337$ K single-crystalline $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ shows a spontaneous magnetization and ferromagnetic hysteresis for fields applied parallel to the tetragonal $[100]$ or $[110]$ directions. For $T < T_{NB} \approx 33$ K, the coercive field is more than one order of magnitude larger compared to that measured in the temperature range $T_{NB} < T < T_{NA}$. The spontaneous magnetization observed in $T_{NB} < T < T_{NA}$ may be attributed to weak ferromagnetism of the Dzyaloshinsky–Moriya type. The behavior of $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ at lower temperatures, $T \leq T_{NB}$, is not yet understood. © 1998 American Institute of Physics. [S0021-8979(98)25211-X]

Compounds containing copper oxide layers or chains and related oxychlorides are of interest because they may become superconductors when doped. Moreover, they show nearly two-dimensional quantum antiferromagnetic^{1,2} or even quasi-one-dimensional behavior.^{1,3,4} Tetragonal $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ is built up of Cu_3O_4 planes with two types of copper atoms (Cu_A, Cu_B),⁵ whereas the orthorhombic $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ contains folded Cu_2O_4 chains along $[100]$, also with two different Cu sites.⁶ The magnetic properties of $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$, to the best of our knowledge, have not been investigated so far. On the other hand, it is well known that in $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ as well as $\text{Sr}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ the moments of the Cu_A and Cu_B atoms order antiferromagnetically at different temperatures $T_{NA} \approx 300, \dots, 380$ K and $T_{NB} \approx 30, \dots, 40$ K, respectively.^{7–9} A small spontaneous magnetization M_0 within the basal plane of the tetragonal lattice has been reported.^{8,9} The presence of this spontaneous magnetization in the temperature range $T_{NB} < T < T_{NA}$ is contradictorily discussed in the literature. The Dzyaloshinsky¹⁰–Moriya¹¹-type interaction leading to weak ferromagnetism has been quoted in Ref. 8. This has been questioned referring to the high degree of crystal symmetry.⁹ Only little is known on the ferromagnetic hysteresis of these materials. Here, we will present some novel results on (i) the magnetic properties of $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ and $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ and (ii) their relation to the lattice structure of these compounds.

Single crystals of $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ were prepared by flux methods. $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ single crystals were grown directly from the stoichiometric melt. The crystals of both compounds were grown up to a size of $20 \times 10 \times 0.1 \text{ mm}^3$. The

characterization with x-ray methods confirmed the reported structure.^{5,6} The magnetic measurements on the single-crystalline samples were performed in a Quantum Design superconducting quantum interference device magnetometer with a maximum field of 5 T and a temperature range from 1.7 to 400 K.

The field dependence of the magnetization M of $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$, measured along the crystallographic a axis for various temperatures is presented in Fig. 1. Below 20 K these curves show a metamagnetic behavior,¹² i.e., an upward curvature in a limited range of H . At a threshold field H_t of 2.6 T the M versus H curve measured at low temperatures jumps between two straight lines. Above the jump, the slope is considerably larger than below. No metamagnetic behavior has been found for $H \parallel b$ or c , i.e., the M versus H curves (not shown in Fig. 1) are straight lines that, for all temperatures, nearly coincide with the straight line measured for $H \parallel a$, above the threshold field. These observations indicate a spin-flop transition,¹³ i.e., a transition from a collinear antiferromagnetic structure with localized moments aligned along the a axis to a configuration perpendicular to the field. Above the spin-flop transition the moments progressively rotate towards the field direction. The most prominent example of compounds with Cu^{++} magnetic moments that undergo a spin-flop transition is $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$.^{14,15} The temperature dependence of the susceptibility χ , shown in Fig. 2, is consistent with the concept of spin flopping. For sufficiently high temperatures the $\chi(T)$ curves are well described by the Curie–Weiss law $\chi = C/(T - \theta)$, with the two fitting parameters C (Curie constant) and θ (paramagnetic Curie temperature). The positive value of θ manifests that the Cu^{++} moments experience, in addition to the dominating

FIG. 1. Field dependence of the specific magnetization of a $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ single crystal, measured for different temperatures parallel to the crystallographic a axis. Below the Néel temperature $T_N \approx 20$ K a spin-flop transition is observed at the threshold field of $\mu_0 H_t = 2.6$ T.

antiferromagnetic coupling, a ferromagnetic exchange interaction. A mean paramagnetic moment of $2.0 \mu_B$ per Cu^{++} ion has been determined from the fitted value of C . For $T < \theta \approx T_N$ and $H < H_t$, the susceptibility χ increases linearly with T for $H \parallel a$ but it remains nearly constant for $H \parallel b$ or c . Obviously, the magnetic coupling between the Cu_2O_4 chains in $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$ is strong enough to allow a three-dimensional antiferromagnetic behavior connected with a spin-flop transition.

Figure 3 shows the magnetization curves of $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ measured for three crystallographic directions at 40 K, i.e., at a temperature between the two reported an-

FIG. 2. Temperature dependence of the reciprocal dc susceptibility $1/\chi$, indicating a paramagnetic Curie temperature, $\theta \approx 21$ K. For H parallel to the a direction, temperatures below T_N and $H < H_t$ (see Fig. 1), $1/\chi$ strongly increases with decreasing temperature, but it is nearly constant for $H \parallel b$ or c .

FIG. 3. Field dependence of the specific magnetization of a $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ single crystal, measured at $T = 40$ K with the magnetic field H applied parallel to different crystallographic directions. For H parallel to $[110]$ or $[100]$ the extrapolation to $H = 0$ gives a finite magnetization $M_0 > 0$.

tiferromagnetic ordering temperatures T_{NA} and T_{NB} . The straight line measured along $[001]$ indicates that this direction is perpendicular to the antiferromagnetically ordered Cu_A^{++} moments. On the other hand, the finite magnetization M_0 measured for $H \rightarrow 0$ in both directions in the basal plane, $[100]$ and $[110]$, indicates the presence of a small spontaneous magnetization as reported in Ref. 8. Furthermore, some metamagnetic behavior at a threshold field H_t is found for $H \parallel [100]$. The temperature dependence of the residual magnetization M_0 , measured for $H \parallel [100]$ and $H \parallel [110]$, is given in Fig. 4. The value of M_0 is not much different for both directions and it vanishes at $T \approx 337$ K, which is close to the reported⁸ upper Néel temperature T_{NA} . Significantly smaller values of M_0 are observed for $H \parallel [100]$, only below the

FIG. 4. Temperature dependence of the residual magnetization M_0 according to Fig. 3, for two directions in the basal plane. M_0 vanishes at $T_{NA} \approx 337$ K, the upper of the two Néel temperatures. $T_{NB} \approx 33$ K is the lower Néel temperature determined from the minimum of the susceptibility.

FIG. 5. Temperature dependence of the threshold field H_t for $H||[100]$ (as defined in Fig. 3).

lower of the two Néel temperatures, $T_{NB} \approx 33$ K, which has been obtained from the singularities of the temperature dependence of the inverse magnetic susceptibility $1/\chi$, not presented in a figure. As shown in Fig. 5, the threshold field H_t increases with increasing temperature, almost in the whole range $T_{NB} < T < T_{NA}$. Contrary to the results of Ref. 8 where ferromagnetic hysteresis was found for $H||[110]$ but not for $H||[100]$, we observed similar types of hysteresis curves for both directions. This is not surprising in view of the square symmetry in the tetragonal basal plane. Typical hysteresis loops measured for $H||[100]$ are presented in Fig. 6. Above the lower Néel temperature T_{NB} the coercive field H_c is more than one order of magnitude smaller than below. Between T_{NB} and T_{NA} , $\mu_0 H_c$ is only about 0.5 mT, for both directions $[110]$ and $[100]$, and does not much depend on temperature. The microscopic mechanism for the magnetic properties of $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$, as presented in Figs. 3–6 and reported in Ref. 8, remains to be clarified. At higher fields the demagnetization curve measured for $H||[100]$ (cf. Fig. 3) approaches a straight line passing through the origin. A similar behavior is observed for certain ferrimagnetic compounds that exhibit field-induced spin canting,¹⁶ which is to some extent comparable to the spin-flop transition discussed for $\text{Ba}_3\text{Cu}_2\text{O}_4\text{Cl}_2$. In the temperature range of $T_{NB} - T_{NA}$, however, ferrimagnetism can be excluded to interpret Fig. 3 because only one type of magnetic ions, Cu_A^{++} , is reported to take part in the ordered magnetic structure.⁷ The anisotropic pseudodipolar interaction between the antiferromagnetically ordered Cu_A and the paramagnetic Cu_B moments has been successfully proposed⁹ to explain, for temperatures above T_{NB} , the presence of a spontaneous magnetization and the metamagnetic behavior of $\text{Sr}_2\text{Cu}_3\text{O}_4\text{Cl}_2$, which has the same structure as $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$. The weak point of this scenario is that it does not work below T_{NB} where both types of Cu moments are antiferromagnetically ordered but a spontaneous magnetization is still present. Weak ferromagnetism of the Dzyaloshinsky–Moriya (DM) type^{10,11} has also been quoted to be the relevant mechanism.⁸ This has been questioned referring to the “perfectly tetragonal structure.”⁹ However, this argument though being valid for $\text{Sr}_2\text{CuO}_2\text{Cl}_2$

FIG. 6. The hysteresis loop of $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$, measured below $T_{NB} \approx 33$ K for $H||[100]$, is characterized by a coercive field $\mu_0 H_c$ of about 15 mT. Above T_{NB} the coercive field is more than one order of magnitude smaller.

does not hold for $\text{Sr}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ in the temperature range above T_{NB} , where in terms of symmetry the Cu_B atoms can be considered to be nonmagnetic. Although both compounds have the same tetragonal space group, weak ferromagnetism is not forbidden for $\text{Sr}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ and $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ because not only the crystal symmetry has to be taken into account but also the symmetry of the zero-order collinear antiferromagnetic order. The problem is, however, that below T_{NB} where two different types of Cu^{++} ions are antiferromagnetically ordered, the DM scenario cannot be used without modification. Thus, the intrinsic magnetic properties of $\text{Ba}_2\text{Cu}_3\text{O}_4\text{Cl}_2$ observed below T_{NB} is not yet understood at all.

The authors are grateful to M. S. Golden for stimulating discussions.

Magnetic, electrical, and structural studies on the metal-insulator transition in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($0 \leq x \leq 4$)

P. Somasundaram, D. Kim, and J. M. Honig

Magnetic transitions and structural transformations have been investigated in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($0 \leq x \leq 4$). It is found from magnetic, resistivity, and thermopower studies that the transition temperature decreases as the Se concentration is increased. The change in magnetization occurs over a 10–15 K range at lower Se concentration, while it broadens to 30 K for an Se concentration of $x=0.5$. Low-temperature studies proved that beyond the composition corresponding to $x=0.5$ the cubic structure is stabilized. The metal-insulator transition beyond the $x=0.5$ composition arises from the electronic rather than from the lattice contribution. © 1998 American Institute of Physics. [S0021-8979(98)40511-5]

I. INTRODUCTION

Chalcogenide spinel compounds have been studied extensively from a variety of viewpoints such as crystal structure, magnetism, superconductivity, and giant magnetoresistance. The thiospinel compound, CuIr_2S_4 , displays a metal-insulator transition around 230 K.¹ The magnetization changes from paramagnetism at high temperatures to diamagnetism at low temperatures and exhibits hysteresis on heating and cooling. Earlier studies have indicated² that the formal valence of Cu and Ir changes as one varies the sulfur composition in $\text{CuIr}_2\text{S}_{4+x}$ ($x=0, 0.1$, and -0.1). We have investigated the magnetic transition and structural transformations in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($0 \leq x \leq 4$). It is found that the transition temperature decreases as the Se concentration is increased. The magnetic, thermopower, and x-ray diffraction studies prove that beyond the composition corresponding to $x=0.5$ the cubic structure is stabilized; the broadened metal-insulator transition beyond this composition is attributed to electronic effects.

II. EXPERIMENTAL METHODS

Stoichiometrically mixed powders of Cu, Ir, S, and Se were fired at 850 °C in sealed quartz ampoules for 8 days. After regrinding, the powders were pelletized and sintered at 850 °C for 4 days. During sintering the ampoules were provided with additional powder of the same composition to minimize the escape of S and Se from the pellet. Powder x-ray diffraction was performed on a diffractometer with a low-temperature attachment. Sintered samples were employed for magnetization studies using a Cryogenic Consultants Limited SQUID magnetometer. Magnetization data were taken at 5 to 324 K in fields up to 6 T. Electrical resistivity was carried out by means of the standard four-

probe technique. Measurements of Seebeck coefficients were performed in an automated thermopower setup.³

III. RESULTS AND DISCUSSION

Powder x-ray diffraction of different compositions at 300 K confirmed that all the samples were monophasic and

FIG. 1. (a)–(d) Warming and cooling magnetization versus temperature data indicating a shift in the metal to insulator transitions of $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ for $x=0, 0.25, 0.5$, and 1.0 .

FIG. 2. X-ray diffraction pattern near the transition for $x=0.1$ (a), 0.5 (b), and 0.75 (c).

cubic in structure at the limit of detection. The variation of magnetization as a function of temperature is given in Figs. 1(a)–1(d) for the compositions $x=0, 0.25, 0.5$, and 1.0 . As can be seen, a change in magnetization occurs over a 10–15 K range at the lower Se concentrations of $x=0$ and 0.25 , while for the composition $x=0.5$ the transition is spread over a region of 30 K. The mean temperature of the transition diminishes as x is increased. The hysteresis on cooling and heating is progressively reduced as the Se concentration is increased. This hysteresis in magnetization is associated with the cubic to tetragonal transition and with the concomitant volume change.

Figure 2 shows the x-ray diffraction pattern obtained while cooling the samples. The transformation from the cubic structure to the tetragonal structure is clearly seen to occur close to the transition temperature for $x=0.1$, while for $x=0.5$ the peaks are also broadened close to the transition because of the lattice strain introduced by the Se substitution. Beyond this composition the cubic structure appears to be stabilized. This trend is also confirmed from the variation of

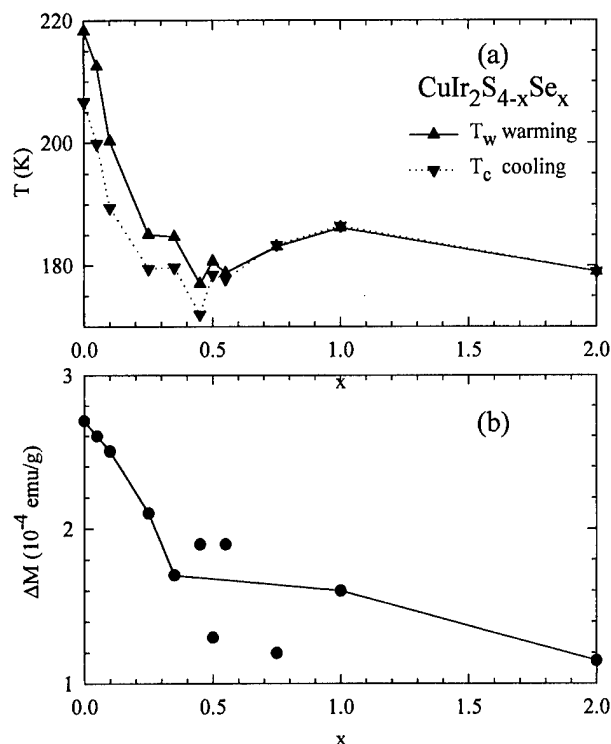

FIG. 3. (a) Variation of transition temperature as a function of composition in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($x=0-2.0$). (b) Variation of the change in magnetization curve as a function of composition in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($x=0-2.0$).

transition temperature T_c as a function of composition, as shown in Fig. 3(a). As can be seen, the hysteresis in magnetization disappears for $x>0.5$, the points beyond that composition are read off from the midpoint of very broad transitions. The irregularities in T_c for $0.3<x<0.5$ arise because of the difficulties in estimating T_c values from the spread-out transition range. From the magnitude of the change in magnetization (between the dia- and para-magnetic states) as shown in Fig. 3(b), it is clear that the number of carriers available for transition is reduced as the Se concentration increases. From resistivity measurements shown in Fig. 4(b), it is found that beyond the $x=0.5$ composition $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ becomes less semiconducting; for $x=4.0$ the material is metallic. For the $x=0.75$ composition, the cubic phase is the stable phase at and below room temperature [see Fig. 2(c)]. The metal-insulator transition beyond the $x=0.5$ composition arises mainly from the electronic rather than from the lattice contribution. This is confirmed from the thermopower and resistivity measurements on selected samples. As can be seen from Figs. 4(a) and 4(b) the transition is broadened for $x=0.55$ and $x=0.75$. The $x=0.75$ sample still undergoes a gradual changeover to a metal, even though it remains cubic. At high temperatures, the Seebeck coefficient approaches a constant value of $-40 \mu\text{V}/\text{deg}$ for all the compositions studied. The variation of Seebeck coefficient is sharpest for $x=0.45$; this coincides with the higher value of resistivity for this sample. At this composition both cubic and tetragonal phases coexist over a 10 K range encompassed by the hysteresis.

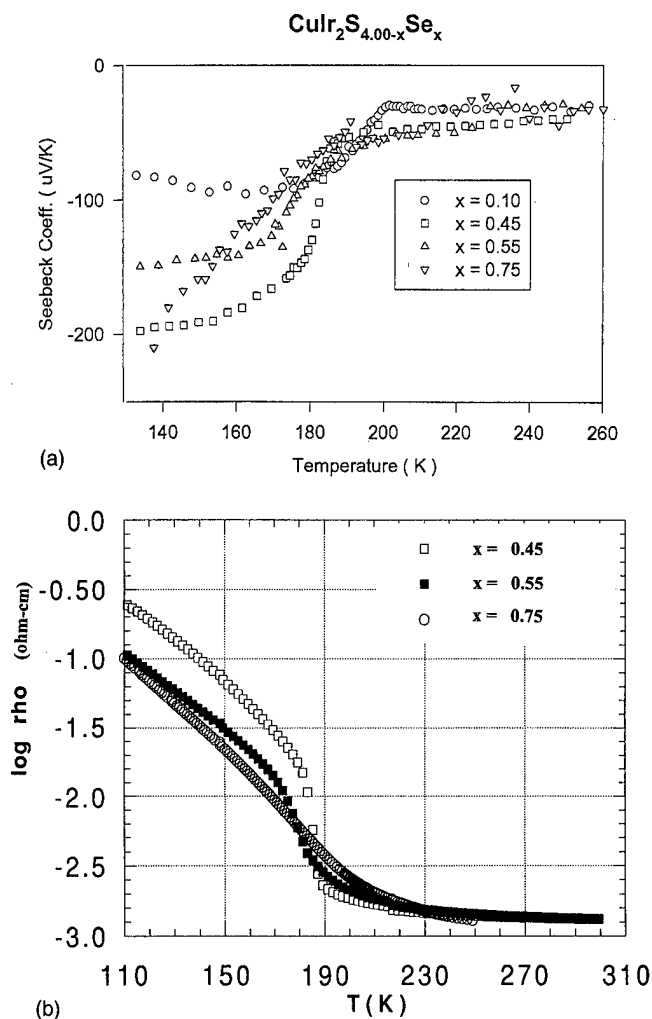

FIG. 4. (a) Measured Seebeck coefficients versus temperature for $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($x = 0.1, 0.45, 0.55$, and 0.75). (b) Variation of resistivity as a function of temperature for $x = 0.45, 0.55$, and 0.75 .

The metal-insulator transition at higher Se compositions could be driven by change in bond angles. Since Se is larger than S, a higher Se concentration stabilizes the larger volume of the cubic structure. The octahedral interstices containing

the Ir atoms increase in size when S atoms are substituted by the larger Se atoms. The transition to the insulating phase can then be attributed to the positional ordering of Ir^{3+} and Ir^{4+} ions at compositions with low Se concentration, similar to the Verwey transition of Fe_3O_4 .^{4,5} This approach is based on the assumption that charge transport involves an activated hopping process of carriers among nearest neighbors of the octahedrally coordinated cationic interstices. Normally, for materials undergoing metal-insulator transitions the switching process in the absence of electronic effects is thermally activated.⁶ However, in the case of $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$, the switching process could be due to the type of electrothermal effects discussed by Chudnovskii *et al.*⁷ Further studies on the electronic structure are essential to determine the precise origin of the metal-insulator transition in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$.

IV. CONCLUSION

We have found that the Se substitution decreases the transition temperature and changes the magnetic properties of $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$. The cubic structure is stabilized for compositions beyond $x = 0.5$; the metal-insulator crossover at higher Se concentrations in the cubic phase is attributed to electronic effects.

Finite size scaling in the thin film limit

The thickness dependent spin-polarized electronic structure of strained thin and ultrathin films of Gd is characterized by a distinct change in the critical exponent λ in the formalism of finite size scaling. The reduced critical exponent in the ultrathin films can be correlated to the increased dominance of the surface magnetic structure and the increasing paramagnetic-like behavior of the bulk. © 1998 American Institute of Physics. [S0021-8979(98)34111-0]

With decreasing film thickness the surface may become increasingly more important for the magnetic ordering of ultrathin films. The surface and bulk electronic structure may adopt the role of “actor” or “spectator” in a ferromagnetic thin film.¹ Electronic structure and its influence will depend in any case, upon electron wave vector² and the film thickness.³

The distinct magnetic properties of the surface as well as the bulk will have significant effects on the finite size scaling behavior of thin films and deviations from the expected finite size scaling behavior⁴

$$\frac{T_C(\infty) - T_C(d)}{T_C(\infty)} = C \cdot d^{-\lambda} \quad (1)$$

can be expected.³ If surface magnetism has a prominent “active” role in the magnetic ordering of ultrathin films it will influence the critical exponent λ . There have been a few examples of deviations in the critical exponent λ in the thin film limit to date.⁵

We studied the finite size scaling behavior for increasingly thinner films of strained Gd^{6,7} with spin-polarized photoemission as described elsewhere.^{2,3} The spin-polarized valence-band photoemission spectra of the strained Gd films have distinct features attributable to the surface and the bulk.^{2,3,8} This permits one to characterize the magnetic behavior of the surface and the bulk separately,^{2,3} as has been done for “unstrained” Gd(0001).⁹ Strained films of gadolinium with an increased lattice constant of approximately 4% have been obtained by growing Gd on a Mo(112) substrate. The half filled 4f shell of gadolinium results in highly localized moments which couple via “RKKY-like” interactions through itinerant valence electron states. The magnetic structure of the system is strongly influenced by the intra-atomic 4f–(5d,6s) wave function overlap and 5d,6s valence electron itinerancy.¹⁰ The electronic valence-band structure, hybridization, and electron itinerancy are all very sensitive to the lattice configuration. Expansive strain of 4% within the hexagonal closed-packed system substantially alters the electronic and magnetic valence-band structure.^{2,3,6} The strain results in increased electron localization of the itinerant valence electrons and therefore enhances local moment ferromagnetism.

The thickness dependent Curie temperature of strained Gd, as determined from spin-polarized photoemission, exhibits a decrease with decreasing film thickness, characteristic of finite size scaling behavior. Figure 1 shows the reduced Curie temperature $[T_C(\infty) - T_C(d)]/T_C(\infty)$ as a function of film thickness d in a logarithmic plot. The data points displayed are for the strained Gd surface (○) [$T_C(\infty) = 370$ K] and the strained Gd bulk (■) [$T_C(\infty) = 340$ K]. Each data point has been determined from the temperature-dependent exchange splitting and spin polarization of the corresponding spin-polarized photoemission features. While there is a wave vector dependence of the exchange splitting and spin polarization,² the Curie temperatures have been deduced from the valence-band spectra with maximum exchange splitting, which is at the Brillouin zone edge.² This Brillouin zone point provides the best indicator of T_C . For comparison, the data for unstrained Gd(0001) (●) [$T_C(\infty) = 293$ K] is shown, which has been extracted from magnetic susceptibility measurements by Farle and co-workers for Gd/W(110).¹¹ In this logarithmic plot the slope of the displayed data points marks the critical exponent λ of the finite size scaling description of the correlation length, as denoted in Eq. (1).

FIG. 1. The reduced Curie temperature $[T_C(\infty) - T_C(d)]/T_C(\infty)$ as a function of film thickness d in a logarithmic plot. The data points displayed are for the strained Gd surface (○) [$T_C(\infty) = 370$ K], the strained Gd bulk (■) [$T_C(\infty) = 340$ K], and the unstrained Gd (●) [$T_C(\infty) = 293$ K]. The latter data are adapted from Ref. 11.

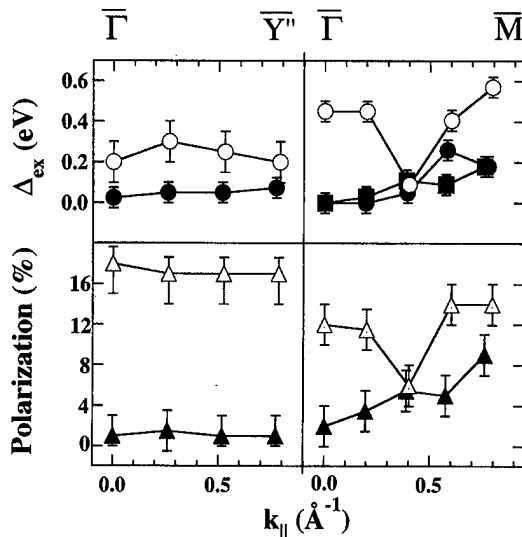

FIG. 2. The exchange splitting (top) and spin asymmetry above background (bottom) of the surface (open symbols) and bulk (filled symbols) spin subbands as a function of wave vector. Data are shown for a 4 ML thick (left) and a 40 ML thick (right) strained Gd film. The data points have been extracted from spin-polarized photoemission spectra.

Clearly the thickness dependence of the reduced Curie temperature for strained thin films of Gd does not follow the expected fixed exponential. A variation of the critical exponent with film thickness is indicated. For film thicknesses of more than approximately 15 monolayers (ML), the critical exponent λ is comparable to the one of the unstrained Gd films, as determined by the similar slope. For the ultrathin films ($d \leq 15$ ML), the slope for strained Gd is reduced by a factor of approximately 4, reflecting a reduced critical exponent λ and decreased sensitivity to finite size scaling. A variation of the critical exponent similar to the one evident for strained Gd is possibly indicated for the unstrained Gd films at thicknesses of less than approximately 8 ML (Fig. 1). The limited data points for the ultrathin films ($d < 10$ ML) that are presented in Ref. 11 make this postulate, however, rather weak. A deviation from the expected finite size scaling behavior is also apparent in Gd/W multilayers for Gd interlayer thickness of less than approximately 15 ML.¹² A crossover from three- to two-dimensionality is possible,^{5,13} but generally dimensionality crossover should result in an increase in the critical exponent¹⁴—not a decrease as observed here.

Concomitant with the variation of the critical exponent for decreasing film thicknesses, the bulk bands of the strained Gd films become paramagnetic-like over an increasingly larger volume in k -space.³ The dominance of the surface magnetic ordering in the ultrathin films is indicated in Fig. 2. Figure 2 plots the exchange splitting (top) and spin asymmetry (bottom) of surface (open symbols) and bulk (filled symbols) spin subbands as a function of wave vector for a 4 ML thick film (left) and a 40 ML thick film (right). While the magnitude of the measured exchange splitting is an indirect indication of the $5d$ moment,¹⁵ the polarization (above background) provides insight into the extent of the magnetic activity, Stoner-like magnetism and/or rigid band ferromagnetism.

The exchange splitting of the bulk bands of the 4 ML thick strained Gd films is small throughout the surface Brillouin zone and exceeds the experimental resolution of 0.05 eV only near the zone edge ($\Delta_{ex} \approx 0.07$ eV), indicative of minimal Stoner-like ferromagnetism, away from the vicinity of the zone edge \bar{Y}'' . There is also no significant polarization (above background) in the region of the Gd bulk bands well away from the Fermi level for any wave vector. The bulk bands of the 4 ML thick Gd films exhibit the paramagnetic-like behavior expected with direct contact to a ferromagnet. For the 40 ML thick films, the magnetic ordering of the bulk bands follows a distinct wave vector dependence with negligible exchange splitting at the zone center $\bar{\Gamma}$ and substantial exchange splitting of approximately 0.25 eV near the zone edge \bar{M} . The spin asymmetry behaves similarly with minimal asymmetry at $\bar{\Gamma}$ and large polarization at \bar{M} . The wave vector dependent exchange splitting of the thicker strained Gd films suggests a change from paramagnetic-like behavior at the Brillouin zone center to Stoner-like magnetism at the zone edge.

The magnetic ordering of the surface behaves differently from that of the bulk. The exchange splitting of the surface state of the 4 ML thick Gd films is of the order of 0.25 eV with little variation for different wave vectors. The spin polarization in the region of the surface sensitive states approaches approximately 17% (above background). The large spin asymmetry and relatively small exchange splitting is indicative of predominantly rigid band magnetism with some Stoner-like ferromagnetic contributions, largely independent of wave vector. This is in contrast to the strong wave vector dependence of the magnetic behavior of the thicker films (40 ML). The surface state exchange splitting is large at the Brillouin zone center ($\Delta_{ex} \approx 0.45$ eV) and at the Brillouin zone edge ($\Delta_{ex} \approx 0.57$ eV). The minimum in the exchange splitting of the surface feature at the Brillouin zone interior ($\Delta_{ex} \approx 0.10$ eV) has been attributed to a wave vector dependent change from a surface state (zone center and zone edge) to a surface resonance (zone interior).² This dip of the surface exchange splitting is reflected in the spin asymmetry, which reduces to 4% in the Brillouin zone interior as compared to 10% at the zone center and 12% at the zone edge.

With decreasing film thickness the region of the Brillouin zone in which the bulk bands are paramagnetic becomes increasingly larger and the surface magnetic ordering increasingly dominant, characterized by diminishing Stoner-like magnetism and strengthened rigid band magnetism. At the same time the bandstructure of the strained Gd films changes significantly. The bulk bands of the thicker films are dispersive with a bandwidth w of approximately 1.6 eV, in contrast to the ultrathin films which appear nearly dispersionless ($w \leq 0.15$ eV). This has substantial consequences for the coherence length which can be estimated as $l \approx \sqrt{w/k_B T_C} a$.¹⁶ Considering that there is a change in the bandwidth w of a factor of approximately 10 with decreasing film thickness, the bulk electron coherence length in the ultrathin films is expected to be much shorter as compared to the thicker films. The surface state electrons of the strained Gd films are considerably more localized as compared to

those of the bulk bands, which is reflected in the narrow bandwidth of $w \leq 0.2$ eV, which is even smaller for the thinner film thicknesses. As a result, the magnetic structure of the increasingly thinner strained Gd films are governed by an *RKKY* interaction that is of increasingly shorter electron coherence length. Finite size effects may become less influential for decreased electron coherence lengths well away from T_C . In any case, the surface state exchange splitting is large at the Brillouin zone center where the band structure is most sensitive to long range order. Some bulk bands exhibit the smallest exchange splitting at zone center. This indicates that the surface may increasingly dominate the thin film magnetism. A deviation from finite size scaling in terms of a reduced critical exponent is expected and consistent with our thickness dependent critical temperature data (Fig. 1). For the limit of $5d$ valence electrons that are highly localized, polarized only by the local $4f$ moments (which themselves do not have to be aligned, due to spin wave excitations), the electron coherence length becomes negligible and a vanishing critical exponent ($\lambda \rightarrow 0$) is expected for the thin film limit ($d \rightarrow 1$), a change distinct from dimensionality effects.

The reduced critical exponent for the ultrathin films is consistent with the magnetic behavior observed in free Gd clusters by Douglass *et al.*^{17,18} Gd clusters of different sizes exhibit very similar magnetic moments per atom (although substantially reduced from that of the bulk gadolinium value). More importantly the Curie temperatures of these small Gd_N clusters ($N=10-92$) are even larger than that of bulk gadolinium. Clearly, finite size scaling behavior fails in the physical world of small clusters and a trend of $\lambda \rightarrow 0$ as $N \rightarrow 1$ is indicated. Indeed ferromagnetic monolayers at finite temperature are known and routinely observed in the thin film limit of ultrathin films. Cluster studies indicate that the atomic coordination number may have significant influence on the magnetic behavior, and are an example of a catastrophic failure of finite size scaling behavior.

In the thin film limit, the apportionment of relative roles in the magnetic ordering of surface and bulk becomes very important for the description of the finite size scaling behav-

ior. For strained Gd films, the short electron coherence length of the *RKKY* interaction is dominating the magnetic behavior of the ultrathin films, with the result of a substantially reduced critical exponent λ . There is no a priori reason why this behavior should be restricted to the strained Gd films grown on a Mo(112) substrate. In fact a similar behavior is anticipated in the "relatively unstrained" Gd(0001) ultra-thin films grown on W(110), although experimental confirmation does not as yet exist.

Phase diagram of a highly diluted, disordered Ising system: The Al-rich, Al-Fe system

J. Restrepo^{a)} and G. A. Pérez Alcázar

Departamento de Física, Universidad del Valle, A.A. 25360, Cali, Colombia

J. M. González

Instituto de Ciencia de Materiales de Madrid-CSIC, Cantoblanco 28049, Madrid, Spain

Disordered solid solutions containing a highly diluted magnetic element in which competitive exchange interactions are present can allow the observation of magnetic ordering (ferromagnetism, antiferromagnetism, and spin-glass behavior) at dilutor element contents different from those corresponding to ordered alloys. In this work we present a simulational study of the magnetic properties of the Al-rich, Al-Fe disordered alloy system, which meets the above mentioned requirements and is therefore a good candidate to show differences between the magnetic phase diagrams corresponding to the ordered and disordered states. Our simulations were carried out on the basis of a randomly site-diluted Ising model, using the Monte Carlo method as energy minimization tool. In our model, the spins of the Fe atoms are assumed to be coupled by a direct nearest-neighbor ferromagnetic exchange J (depending on the Al concentration), and by an Al-mediated antiferromagnetic superexchange interaction $-\alpha J$. Our results suggest the presence of ferromagnetic order for Al concentrations higher than those for which that order disappears in ordered alloys and the occurrence, for Fe atomic percentages between 10% and 25%, of a re-entrant spin glass phase whose freezing temperature decreases with the degree of dilution. © 1998 American Institute of Physics. [S0021-8979(98)34211-5]

I. INTRODUCTION

Most of the work on the Al-Fe alloys in the literature,^{1,2} focuses on systems where the atoms have well defined ordered positions into the crystalline structure. These works, which cover exclusively the Fe-rich region of the phase diagram (Fe contents above 50 at. % Fe), show that, in the vicinity of 30 at. % Al and in the temperature region between 90 and 170 K, there is a multicritical point in the magnetic phase diagram where the paramagnetic, ferromagnetic, and spin-glass phases meet. In contrast with the magnetic behavior of these ordered systems, the disordered alloys, in which the atoms are randomly distributed in the crystalline lattice, still exhibit³ ferromagnetism at 50 at. % Al. Further theoretical work,⁴ suggests that this ferromagnetic phase could be even present at higher Al concentrations. Very recently, a Monte Carlo study⁵ of the magnetic properties of Fe-rich, Al-Fe disordered alloys, based on a site-diluted Ising model, in which an explanation of why the Ising model can be appropriate is given, has predicted, in agreement with experimental data,³ a smooth decrease of the Curie temperature with the increase of the Al content. That decrease goes beyond 30 at. % Al, the concentration for which the ordered alloys loose their long range magnetic order.¹ In the present work we report simulation studies of the magnetic phase diagram of Al-Fe disordered alloys with Al contents higher than 50 at. %. We simulate the magnetic properties of these alloys in the framework of a random-site diluted Ising model with ferromagnetic and antiferromagnetic bonds for the first and second coordination shells, respectively. The tempera-

ture evolution of the magnetization, the Edwards-Anderson parameter, the magnetic susceptibility and, the magnetic specific heat are presented and discussed.

II. DESCRIPTION OF THE MODEL

In order to study the magnetic properties of Al-Fe disordered alloys we have considered a diluted and random site Ising model with nearest-neighbors (nn) and next-nearest-neighbors (nnn) interactions. The zero-field Hamiltonian of this model can be written as

$$H = - \sum_{\langle i,j \rangle} J_{ij} \sigma_i \sigma_j - \sum_{\langle i,j \rangle} J_{ij}^* \sigma_i \sigma_j, \quad (1)$$

(nn) (nnn)

where $J_{ij} > 0$ is the ferromagnetic exchange parameter corresponding to (nn) Fe-Fe pairs, $J_{ij}^* = -\alpha J_{ij} < 0$ is the antiferromagnetic superexchange parameter corresponding to (nnn) Fe-Fe pairs (which are separated by an Al atom), α is the competition parameter taken to be 0.05,⁴ and $\sigma_i = \pm 1$ or 0, depending on the occupation of the i th site by an Fe atom or an Al one, respectively. In order to consider site dilution the following probability distribution was simulated,

$$P(\epsilon_i) = p \delta(\epsilon_i - 1) + q \delta(\epsilon_i), \quad (2)$$

where p and q are the percent concentration of magnetic and nonmagnetic sites ($p + q = 1$) and $\epsilon_i = 1$ or 0, depending on the i th site occupation by a magnetic or nonmagnetic atom, respectively. The (nn) and (nnn) bonds are determined according to $J_{ij} = \epsilon_i \epsilon_j J$ and $J_{ij}^* = -\alpha \epsilon_i \epsilon_j J$, respectively.

As it has been already shown,³ the increase of the Al content produces an increase of the lattice parameter, due to the large atomic size of the Al atoms. Therefore, the Fe-Fe

^{a)}Electronic mail: johans@calima.univalle.edu.co

exchange integral should depend on the Al concentration q . Here, it was taken to vary from 50 up to 90 at. % Al according to³

$$J(q) = J_1 - J_0 q, \quad (3)$$

where $J_1 = 12.85$ meV and $J_0 = 0.95J_1$ according to previous works,^{3,4} for which a good agreement with experimental data was obtained.

In the case of (nn) interactions, $J_{ij} = 0$ for the diluted Fe–Al and Al–Al bonds and J_{ij} is given by Eq. (3) for ferromagnetic Fe–Fe bonds. For (nnn) interactions, $J_{ij} = -\alpha J$ only for those Fe atoms which are separated by an Al one, and $J_{ij} = 0$ otherwise.

In agreement with the known crystalline structure of these alloys series, our simulated system consists on a three-dimensional (3D) bcc structure ($11 \times 11 \times 11$ atoms) with periodic boundary conditions. In order to minimize Eq. (1), we have used the standard Monte Carlo method implemented with the Metropolis dynamics. Each Monte Carlo step (MCS) involves the evaluation of the spin-flip probability at all the different magnetic sites in the lattice. The maximum number of Monte Carlo steps was taken to be 10 000 MCS. The magnetization, the magnetic energy, the magnetic susceptibility taken from the fluctuations in the magnetization, and the Edwards–Anderson (EA)⁶ parameter, were evaluated. MCS averages of these quantities, were considered in order to give thermodynamic equilibrium values for each particular system (atomic distribution) realization. We have repeated the relaxation process for different system realizations (corresponding to the same q value and having different random Fe and Al atomic distributions) and carried out configurational averages. All the different runs were performed, simulating a typical zero field cooling (ZFC) measurement, by applying, during the heating process and data collection, a 100 Oe field. The critical temperature T_c values, linked to a ferroparamagnetic transition, for each considered q value, were determined from the maximum observed in the temperature dependence of the susceptibility and the magnetic specific heat.⁷ The freezing temperatures associated to the spin glass transition are obtained from the temperature dependence of the Edwards–Anderson parameter q_{EA} .^{8,9}

III. RESULTS AND DISCUSSION

Figure 1 shows (for q ranging from 0.60 up to 0.90) the temperature dependences of the magnetic specific heat C_m , and the magnetic susceptibility χ . From the maximum of these curves, an estimation of the T_c value was obtained. It is remarkable in Fig. 1 the rounded broad maximum present in the C_m vs T curves corresponding to high Al contents, which is possibly associated to a large negative critical exponent.¹⁰ This behavior is characteristic of a spin glass¹⁰ phase. In order to compare the T_c values obtained from C_m and χ , we have defined the β parameter, given by $\beta = T_c[C_m]/T_c[\chi]$. In the range 50–70 at. % Al, the β value was 1.0. For higher Al contents, the obtained β values are given in Table I. For 75 at. % Al and higher Al contents, a shift between the cusps of the C_m vs T and χ vs T curves, increasing with the dilution increase is observed. Such behavior has already been

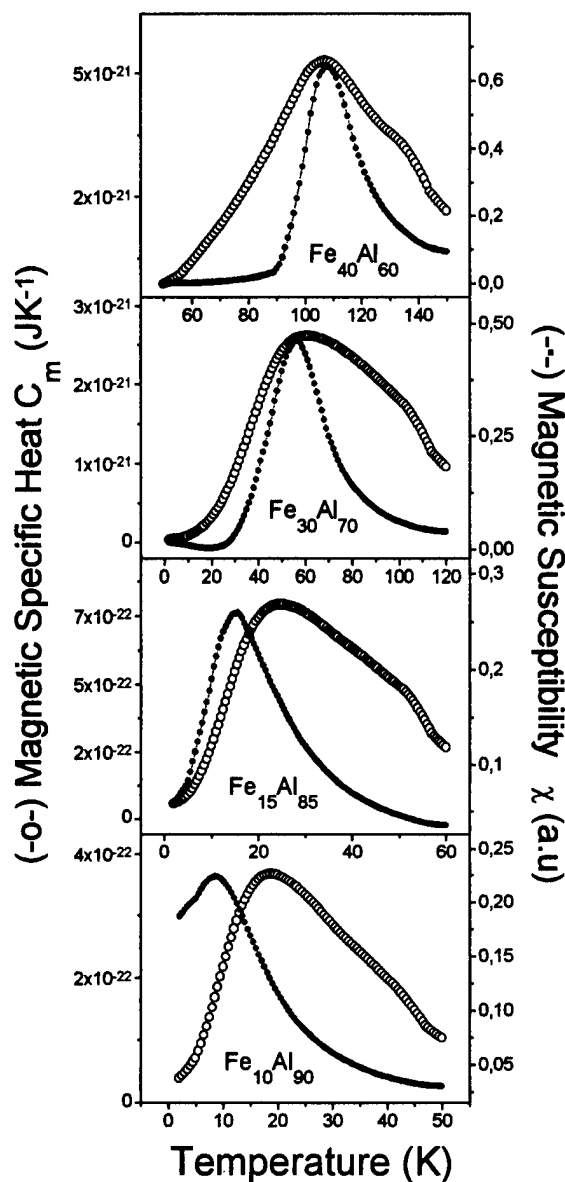

FIG. 1. Magnetic specific heat C_m (open circles) and susceptibility χ (solid circles), dependences on the temperature for different q values.

observed in magnetic specific heat $C_m(T)$ measurements obtained in spin glasses,¹⁰ where the maxima temperatures range between 1.3 and 1.8 T_f (T_f = freezing temperature obtained by susceptibility measurements).

In order to obtain the freezing temperature, an extrapolation to the temperature axis^{8,9} of the q_{EA} data correspond-

The dashed lines correspond to the polynomial, through which and by extrapolation, the freezing temperatures were obtained.

ing to temperatures below the inflection point by means of a third order polynomial, was performed as it is shown in Fig. 2. This figure shows the q_{EA} parameter and magnetization dependences on the temperature for different q values. Up to 75 at. % Al, the system becomes saturable and the thermal evolutions of M/M_s and q_{EA} agree with a ferromagnetic behavior. Also, the C_m and χ peaks are practically coincident, as expected for a well defined ferroparamagnetic transition. In contrast with this behavior, for Al contents higher than 75 at. % Al, the magnetization does not reach its saturation value, as it can be observed for 80 and 90 at. % Al in Fig. 2. The observed differences (see Table I), in this Al concentration range, between the C_m and χ peak temperatures, are, as already indicated, in agreement with the typical experimental results obtained in spin glasses. On the other hand, the difference between the T_f values, obtained by extrapolation from the q_{EA} vs T curves, and those corresponding to T_c and obtained from the χ vs T curves, define, in the high Al content region, two clearly distinguishable phases.

In Fig. 3 we show the proposed magnetic phase diagram summarizing the results of the present study. We would like to stress that the data shown in this figure exhibit two remarkable features. First, in contrast to the behavior of the ordered alloys, a pure ferromagnetic phase can be identified for Al concentrations of up to 75 at. %. Arguably results from the disorder, due to which the probability of finding

FIG. 3. Disordered Al-rich, Al-Fe magnetic phase diagram proposed in the present work.

two Fe atoms into the first and second coordination shell of a given Fe atom (forming a sort of Fe cluster) is nonzero even for large Al contents (this can be readily shown by considering a binomial atomic distribution). Second, the data strongly suggest the occurrence of a re-entrant spin glass phase for Al contents higher than 75 at. % Al. This can be attributed both to the disorder and to the competition between the ferro and antiferromagnetic exchange couplings, which plays a relevant role in this range of Al concentrations and temperature.

Processing effects on the magnetostrictive and physical properties of SmFe_2 /metal composites

F. E. Pinkerton,^{a)} T. W. Capehart, J. F. Herbst, E. G. Brewer, and C. B. Murphy
*Physics and Physical Chemistry Department, General Motors Research and Development Center,
30500 Mound Road, Warren, Michigan 48090-9055*

Hot pressed SmFe_2/Fe and SmFe_2/Al composites combine the large magnetostriction of SmFe_2 with the mechanical robustness of the Fe or Al matrix. Here we report the dependence of the magnetostriction, density, and mechanical hardness on processing parameters, specifically on the SmFe_2 volume fill fraction and the consolidation temperature. The magnetostriction increases monotonically with increasing SmFe_2 content, but both the density and hardness decrease; low fill fraction composites are within 10% of theoretical density and have hardnesses of 40–85 Rockwell *B*, whereas hot pressed SmFe_2 powder alone has high porosity (exceeding 30%) and is too soft to register on the Rockwell *B* hardness scale. The best combination of properties lies in the range of 40%–60% SmFe_2 . Similar competition between magnetostriction and physical properties is observed as a function of the temperature used to consolidate the samples. The magnetostriction falls slowly as the hot press temperature increases, probably as a result of chemical reaction between the SmFe_2 phase and the matrix metal. On the other hand, higher temperature improves the consolidation, resulting in higher density and hardness. These results demonstrate that the magnetostrictive and physical properties of SmFe_2 composites can be tailored by adjusting the fill fraction and processing temperature. © 1998 American Institute of Physics.

I. INTRODUCTION

Magnetostrictive materials show considerable promise as the active elements in automotive force and torque sensors (see, e.g., Ref. 1). We have recently reported the development of hot pressed magnetostrictive composites comprised of the magnetostrictively active compound SmFe_2 embedded in an Fe or Al matrix.² We use SmFe_2 , with saturation magnetostriction $\lambda_s = -1560$ ppm,³ because of its reduced cost compared to TbFe_2 -based compositions; we expect that similar results would be obtained with TbFe_2 and $(\text{Tb}, \text{Dy})\text{Fe}_2$. Our preliminary work concentrated on composites made with 50% SmFe_2 powder by volume in which we achieved saturation magnetostrictions $|\lambda_s| = 280$ –440 ppm. These values are roughly an order of magnitude larger than those of magnetostrictive steels such as T250 maraging steel ($\lambda_s = 29$ ppm), and the composites offer mechanical integrity considerably superior to that of pure SmFe_2 . The SmFe_2 component was obtained either from single-phased annealed SmFe_2 ingot or from melt-spun and crystallized SmFe_2 ribbons. In the latter case the composites were good permanent magnets in addition to being highly magnetostrictive.

This article examines the composite's magnetostriction as the fill fraction of SmFe_2 powder is varied from 20% to 100% by volume. We also report on changes in magnetostriction as the hot press temperature is varied between 530 and 730 °C (Fe) or between 500 and 620 °C (Al). We additionally monitor two important physical properties of the composite, namely the physical density ρ , which is a mea-

sure of the porosity of the sample, and the Rockwell hardness, which we use as a relative indication of the mechanical integrity of the composite.

II. EXPERIMENTAL PROCEDURES

This work considers composites made from annealed single-phased SmFe_2 ingot; we expect that similar results would be obtained for our ribbon-based composites. Composites were prepared as detailed previously.² Starting ingots having the $\text{Sm}_{0.333}\text{Fe}_{0.667}$ stoichiometry were cast by induction melting, then annealed for either 100 or 270 h at 700 °C to obtain single-phased ingots of SmFe_2 . The 100 h anneal was sufficient to produce pure SmFe_2 material, and no further benefit was derived from annealing for the longer time; both anneals generated identical SmFe_2 ingots as determined by x-ray diffraction analysis. The ingots were high energy ball milled for 5 mins in a SPEX 8000 mixer/mill to obtain SmFe_2 powder. The powder was mixed with either Fe or Al powder and hot pressed at 95 MPa to obtain a composite cylinder 12.7 mm in diameter and about 7 mm high. A series of composites was hot pressed at 610 (Fe) or 540 °C (Al) in which the volume fraction of SmFe_2 was varied between 20% and 100%. A second series of composites was fabricated in which the SmFe_2 fraction was fixed at 50% by volume while the hot press temperature was varied between 530 and 730 °C for Fe, and between 500 and 620 °C for Al.⁴

The magnetostrictive strain λ as a function of the applied magnetic field H was measured using constantan strain gauges in a half-bridge configuration, mounted on the flat face of the cylindrical sample. In this arrangement two strain

FIG. 1. Magnetostriction $2/3(\lambda_{||} - \lambda_{\perp})$ as a function of applied magnetic field H for hot pressed SmFe_2/Fe composites made at various SmFe_2 fill fractions.

gauges simultaneously measure the strain $\lambda_{||}$ parallel to the direction of H and the strain λ_{\perp} in the direction perpendicular to H , providing a direct measurement of the difference $(\lambda_{||} - \lambda_{\perp})$. For an isotropic magnetostrictor (as is often assumed to be the case for randomly oriented polycrystalline materials such as these composites) and in a magnetic field large enough to saturate the magnetostrictive response this difference is proportional to the saturation magnetostriction λ_s :

$$\lambda_s = \frac{2}{3} (\lambda_{||} - \lambda_{\perp}).$$

Magnetostrictive strains were measured in magnetic fields up to ± 19 kOe.

The physical density ρ was determined from the sample dimensions and weight. The hardness was obtained using a standard hardness tester on the Rockwell B scale.

III. RESULTS AND DISCUSSION

The magnetostrictive strains $\lambda = 2/3(\lambda_{||} - \lambda_{\perp})$ as functions of the applied magnetic field H are shown for various SmFe_2 fill fractions in Fig. 1 for composites made with Fe. A similar set of curves is generated for composites with Al. As expected, composites with larger SmFe_2 fill fractions show higher magnetostrictive strains. Recently a mathematical model of magnetostriction in composite materials was developed which describes the observed fill fraction dependence rather well.⁵

None of the magnetostriction curves in Fig. 1 reach saturation in the maximum applied field of 19 kOe (the same is true for composites with Al). Somewhat surprisingly, it is easier to saturate the magnetostriction as the SmFe_2 content increases, with the pure SmFe_2 sample having the most nearly saturated appearance. The origin of this effect is not understood. To quantify this observation, the saturation magnetostriction λ_s was estimated by performing a least squares fit of each magnetostriction curve to the empirically chosen formula

$$\lambda(H) = \lambda_s [1 - e^{-(H-h_c)/h_0}],$$

where $\lambda_s = 2/3(\lambda_{||} - \lambda_{\perp})(H \rightarrow \infty)$ and h_c and h_0 are fitting parameters. By comparing the magnetostriction at 19 kOe,

FIG. 2. Ratio λ_{19}/λ_s of the magnetostriction $\lambda_{19} = 2/3(\lambda_{||} - \lambda_{\perp})$ measured at the maximum applied field of $H = 19$ kOe to the extrapolated saturation magnetostriction $\lambda_s = 2/3(\lambda_{||} - \lambda_{\perp})$ in the limit of very large field. The lines are guides to the eye.

$\lambda_{19} = 2/3(\lambda_{||} - \lambda_{\perp})(H = 19 \text{ kOe})$, to λ_s the relative degree of saturation can be assessed. The ratios λ_{19}/λ_s are shown in Fig. 2 for Fe (open circles) and Al (filled circles) composites. While composites at high SmFe_2 fill fraction are close to saturation ($\lambda_{19}/\lambda_s \approx 1$), at low fill fractions they are far from saturation, especially with Al.

The dependence of $2/3(\lambda_{||} - \lambda_{\perp})$ at 19 kOe on the SmFe_2 fill fraction is shown in Fig. 3 for the composites made with Fe. Also shown is the physical density ρ normalized to its theoretical value $\rho_{\text{theoretical}}$ calculated from the volume fraction of the two constituents and the known densities of the SmFe_2 and Fe components. The value of $\rho_{\text{theoretical}}$ is only approximate since it does not take into account any chemical reaction between the two constituents, which would form additional phases having different densities. Nevertheless, the ratio $\rho/\rho_{\text{theoretical}}$ serves as a rough measure of the porosity of the sample. The porosity at SmFe_2 fill fractions up to 50% is less than 15%, and decreases as the SmFe_2 fraction drops. At high fill fractions the porosity is quite large, reaching a value exceeding 30% in a sample comprised of pure

FIG. 4. Dependence of the magnetostriction $2/3(\lambda_{||} - \lambda_{\perp})$ at $H = 19$ kOe (●), the density ρ normalized to the theoretical density $\rho_{\text{theoretical}}$ (□), and the hardness (▼) on the volume fraction of SmFe₂ in hot pressed composites with Al.

hot pressed SmFe₂ powder. Finally, the hardness is shown on Fig. 3 as the filled inverted triangles. The pure SmFe₂ sample is too soft to register on the Rockwell *B* scale, but the hardness increases steadily as the SmFe₂ fraction decreases, reaching nearly 90 Rockwell *B* at low fill fraction.

Figure 4 shows similar data for composites made with Al. The trends in magnetostriction and density are very similar to those observed in the Fe composites. The density ratios of the Al composites tend to be slightly higher than those of the corresponding Fe composites, probably because of the greater malleability of Al. The hardness is substantially reduced in the Al composites and is also quite variable. This can be associated with the mechanical softness of annealed Al, and suggests that the hardness of the Al composites is quite sensitive to the details of the hot press, in ways which are currently not fully controlled.

The variation of these properties with hot press temperature is shown in Figs. 5 and 6 for composites made at 50 vol % SmFe₂ with Fe and Al, respectively. In both cases the magnetostriction decreases slowly with increasing hot press temperature. We ascribe this loss to chemical reaction between the SmFe₂ and Fe or Al matrix at elevated tempera-

FIG. 5. Dependence of the magnetostriction $2/3(\lambda_{||} - \lambda_{\perp})$ at $H = 19$ kOe (●), the density ρ normalized to the theoretical density $\rho_{\text{theoretical}}$ (□), and the hardness (▼) on the hot press temperature in 50 vol % SmFe₂ composites with Fe.

FIG. 6. Dependence of the magnetostriction $2/3(\lambda_{||} - \lambda_{\perp})$ at $H = 19$ kOe (●), the density ρ normalized to the theoretical density $\rho_{\text{theoretical}}$ (□), and the hardness (▼) on the hot press temperature in 50 vol % SmFe₂ composites with Al.

ture, which converts part of the material at the particle interfaces into additional, low magnetostrictive rare earth-Fe or rare earth-Al phases. On the other hand, higher hot press temperatures substantially improve the consolidation, resulting in better density and hardness values.

In conclusion, the magnetostriction of SmFe₂/metal composites scales in the expected fashion with the magnetostrictive SmFe₂ content. The best mechanical properties are found at relatively low fill fractions (20%–40%), where the porosity is around 10% and the hardness exceeds 40 (Al) or 80 (Fe) Rockwell *B*. The consolidation temperature also strongly influences the properties; with higher hot press temperature giving reduced magnetostriction but improved consolidation. These results indicate that some tailoring of the materials properties can be done if some of the high magnetostriction can be sacrificed in favor of mechanical properties. Taken as a whole, these results begin to establish limits on the SmFe₂ fill fraction and the hot press temperature which simultaneously provide significant magnetostriction and reasonable mechanical properties.

⁴We have no reason to expect that uniaxial hot pressing introduces significant texture. Orientation during hot pressing is known to occur in Nd-Fe-B due to a combination of diffusion slip and stress-assisted preferential grain growth during deformation of the tetragonal Nd₂Fe₁₄B phase [see, e.g., R. K. Mishra, J. Appl. Phys. **62**, 967 (1987)]. Even so, Nd-Fe-B magnets develop a texture of no more than 10% during hot pressing; full orientation requires an additional die upsetting step. We have no evidence that any similar mechanism is operative in the cubic RFe₂ phase.

Magnetomechanical coupling and elastic moduli of polymer-bonded Terfenol composites

J. Hudson, S. C. Busbridge, and A. R. Piercy^{a)}

Department of Mechanical and Manufacturing Engineering, University of Brighton,
Brighton BN2 4GJ, United Kingdom

The dependence of coupling coefficient (k) and elastic moduli (E_H and E_B) on particle size and volume fraction of Terfenol powder in polymer-bonded composites has been investigated. Materials were prepared with powder in five size ranges between 106 and 710 μm and in three volume fractions (V_F). The moduli show a ΔE effect, which is negative for small bias fields and positive for larger fields. E_H is found to be independent of particle size and to vary with V_F in agreement with model predictions. The maximum value of k , for each sample, is found to be independent of both particle size and V_F and a simple model is presented which predicts this behavior and indicates that the low values of k_{max} arise mainly from the low modulus of the epoxy binder. © 1998 American Institute of Physics. [S0021-8979(98)25311-4]

INTRODUCTION

Polymer-bonded Terfenol powder composite materials are the focus of increasing attention¹⁻⁴ for applications at higher frequencies than are possible with bulk Terfenol. There does not, however, appear to be any published work aimed at investigating the dependence of the magnetomechanical properties of these materials on composition parameters. The present work, which forms part of a program designed to elucidate the variation of properties with particle size and volume fraction, reports results for the magnetomechanical coupling coefficient (k) and elastic moduli at constant H and constant B (E_H and E_B , respectively).

EXPERIMENT

The composite samples were prepared from Terfenol powder in five particle-size ranges (106–150, 150–212, 212–300, 300–500, and 500–710 μm) each in three volume fractions (nominally, 55%, 62% and 70%) with epoxy (Araldite AY103/HY951) as the binding material. For each composition, two rectangular samples, of size 50×10×7 mm, were prepared using a cold compression-moulding technique under pressures of 20–150 MPa applied to the largest-area face of the samples. The range of volume fractions used was limited by the difficulty of maintaining uniformity for lower concentrations and of avoiding porosity for higher concentrations.

Static and dynamic magnetomechanical properties were measured at room temperature, with zero stress bias. The bias field, which was provided by an electromagnet, was applied along the long axis of the sample, which was also the direction of measurement. E_H and E_B were determined from the resonance and antiresonance frequencies (f_{max} and f_{min}), respectively, which were obtained from the frequency dependence of the magnitude of the electrical impedance of a 70-turn coil around the sample.

The coupling coefficient k was evaluated by three methods:

(a) from f_{max} and f_{min} using

$$k = \sqrt{1 - \frac{f_{\text{max}}^2}{f_{\text{min}}^2}}, \quad (1)$$

(b) from analysis of the complex impedance loop,
(c) by the “three-parameter method” using

$$k = \sqrt{\frac{d_{\sigma}^2 E_H}{\mu_{\sigma}}}, \quad (2)$$

where d_{σ} and μ_{σ} are the dynamic d coefficient and permeability, respectively, and E_H , was obtained from f_{max} . All the properties were determined as functions of the bias field.

RESULTS AND DISCUSSION

The variation of E_H and E_B with the bias field and the associated k dependence [from Eq. (1)] are shown in Figs. 1 and 2, respectively, for the sample having a particle size of 300–500 μm and 64% volume fraction. This bias-field dependence, in which E_H decreases to a minimum value at the

FIG. 1. Typical variation of E_H and E_B with bias field.

^{a)}Electronic mail: a.r.piercy@bton.ac.uk

FIG. 2. Typical variation of k with bias field.

bias field corresponding to maximum k and then increases, was typical of all samples. The values of E_H found here are similar to those obtained by Sandlund *et al.*¹ The negative ΔE effect was also observed in earlier work,^{1,3} although the positive ΔE at higher bias fields was not reported and Ruiz de Angulo *et al.*³ also observed a much more flat dependence of k on the bias field. The form of behavior found here, apart from the negative ΔE region, is more reminiscent of that for bulk Terfenol.

A more detailed comparison between the present work and the earlier publications is difficult because information on particle size is not given in Sandlund *et al.*¹ and in Ruiz de Angulo *et al.*³ it was "less than 125 μm ." It is likely that a wider range of particle size, in each sample, was used in the earlier work. Furthermore, the volume fractions employed here are probably lower than in the earlier work and it is not possible to compare the properties of the binders used.

The dependence of E_H (at the bias field for maximum k) on volume fraction (V_F) is given in Fig. 3 where the solid lines represent the limiting theoretical values of the modulus given by the models of Ravichandran,⁵ calculated using the manufacturer's value of 2.7–3.3 GPa for the modulus of the epoxy and 70 GPa for bulk Terfenol. Although the dependence of E_H on V_F is weak, it is clear that within experimen-

FIG. 3. The variation of E_H with volume fraction for all samples.FIG. 4. The variation of k_{max} with volume fraction for all samples.

tal uncertainty there is good agreement with the model, which gives values very different from a linear interpolation. No systematic dependence of E_H on particle size was found.

Figure 4 shows the dependence of the maximum value of k (which occurs at a bias field of about 60 kA m^{-1} for each sample) on V_F and clearly, within the experimental uncertainty, k_{max} is independent of V_F . Similarly, no systematic dependence on particle size was observed.

The average value for k_{max} obtained using Eq. (1) was 0.26, while Eq. (2) and the complex impedance loop, which we believe generally provide the more accurate measures of k , gave an average value of 0.15. This value for k is considerably smaller than that reported by Sandlund *et al.*¹ although it is not clear, in the latter case, whether a dynamic value for the d coefficient was used, as in our work, with Eq. (2). Our measurements show that incremental d coefficients, obtained from static magnetostriction curves, are at least a factor of 2 greater than the dynamic values obtained by alternating excitation.

In modeling the dependence of k on V_F we consider the V_F dependence of the three parameters in Eq. 2. Our measurements of static properties indicate that the saturation magnetostriction is independent of V_F in the range used and that the magnetization varies in proportion to V_F . We, therefore, take the dynamic susceptibility χ to be proportional to V_F and this is confirmed by our experimental measurements.⁷ The ratio d/χ is a function of the magnetization process and λ_{sat}/M_s only⁶ and we assume that the magnetization process does not vary with V_F . This leads, with the above assumptions, to the prediction that d is independent of V_F , which is again confirmed by our measurements.⁷

Equation (2) then leads to

$$k^2 = k_1^2 \left(\frac{E}{E_1} \right) \frac{(1 + \chi_1)}{(1 + \chi_1 V_F)}, \quad (3)$$

where the subscript "1" refers to the values for a composite with $V_F = 1$, which we note will not be the values measured for bulk Terfenol, but rather for a hypothetical 100% dense, randomly orientated powder material. Our measurements⁷ of dynamic susceptibility give an extrapolated value of $\chi_1 = 1.4$ and taking (E/E_1) from Fig. 3 into Eq. (3) with k_1

$=0.5$ leads to a predicted dependence for k shown by the solid line in Fig. 4. The model, therefore, predicts that k_{\max} is virtually independent of V_F in the range used, in agreement with the experimental results within experimental uncertainties.

The low value of k_{\max} measured (and predicted) for our materials can be seen from Eq. (3) to be due principally to the low modulus ratio (E/E_1) which, in turn, arises from the low elastic modulus of the epoxy. Use of a higher-modulus binder should, therefore, lead to an increase in k_{\max} as well as an increase in the forces generated by the material.¹ On the other hand, if the considerations which lead to Eq. (3) are valid, then increase in V_F (within practical constraints) would not lead to a significant increase in k .

The not-inconsiderable variations observed (Figs. 3 and 4) in the measured properties for similar volume fractions and particle sizes arise, we believe, from two main sources: variations in the elastic modulus of the epoxy, due to the small quantities used in mixing the two components; and variations in the orientation of the magnetic particles.

CONCLUSION

It has been shown both experimentally and theoretically that the magnetomechanical coupling coefficient in these

composites is essentially independent of both particle size and volume fraction and the relatively low value of the coupling coefficient has been shown to arise mainly from the low modulus of the epoxy binder. The elastic moduli are shown to be independent of particle size and to follow the model dependence on volume fraction.

First-principles theory of magnetoelastic coupling and magnetic anisotropy strain dependence in ultrathin Co films on Cu(001)

A. B. Shick, D. L. Novikov, and A. J. Freeman

Department of Physics and Astronomy, Northwestern University, Evanston, Illinois 60208-3112

The magnetoelastic coupling and magnetic anisotropy energy (MAE) of (i) an uncovered and (ii) a Cu-capped Co overlayer on Cu(001) are determined employing a self-consistent relativistic spin-polarized version of the total-energy full-potential linearized augmented plane-wave (FLAPW) method and the magnetic torque method. Layer-resolved contributions to the magnetoelastic coupling and MAE are obtained. We find surface magnetoelastic coupling coefficients to be positive for the Co layer and negative for the Cu substrate and cap layers. A substantial difference of magnetoelastic coupling coefficients for thin films as opposed to bulk is demonstrated, which causes a negative magnetostriction coefficient (λ_{001}) for uncovered Co overlayer and a positive λ_{001} for the Cu-capped Co overlayer on Cu(001). © 1998 American Institute of Physics.

[S0021-8979(98)40611-X]

Recent experimental investigations of ultrathin Co films on Cu(001) demonstrate the existence of a magnetoelastic coupling contribution to the magnetic anisotropy energy (MAE) due to tetragonal strain.¹ Chappert and Bruno² considered a magnetoelastic strain relaxation contribution to the surface MAE due to interfacial dislocations, and pointed out that homogeneous strain does not contribute to the surface MAE. However, O'Handley and co-workers³ found a magnetoelastic homogeneous strain contribution to the surface MAE which is caused by a substantial difference between magnetoelastic coupling constants for bulk and surface. The Néel pair-interaction model analysis⁴ and general group symmetry considerations⁵ both show that in addition to bulk magnetoelastic coupling coefficients, surface magnetoelastic coupling coefficients must be introduced to describe true ultrathin film magnetoelastic coupling.

Here we report results for first-principles calculations of the surface magnetoelastic coupling constant and the magnetostriction coefficient for an uncovered and a Cu-capped Co overlayer on Cu(001) in order to investigate quantitatively this reverse magnetostriction effect. The full-potential linear-augmented plane-wave (FLAPW) method⁶ is used to obtain self-consistent solutions of the Kohn–Sham–Dirac equations in terms of a second variation for SOC;⁷ the total-energy and MAE dependence on surface strain are employed to determine the surface magnetoelastic coupling constant and magnetostriction coefficients. We used a symmetric slab model consisting of (i) five Cu substrate layers and a pseudomorphic Co overlayer on each side (Co/5Cu) for a Co overlayer on Cu and (ii) three Cu substrate layers and Cu-capped Co overlayers on each side (Cu/Co/3Cu) for the Cu-capped Co overlayer on Cu. The ideal fcc structure with a lattice constant $a=6.83$ a.u. is assumed for the Cu substrate layers while the vertical Co–Cu distance is varied as a parameter.

The 55 special k points mesh in the irreducible part of the two-dimensional Brillouin zone (2D BZ) is used for the self-consistent calculations for the perpendicular spin quantization axis. Lattice harmonics with angular momentum l up to eight are used to expand the charge and spin densities and

wave functions within the muffin-tin sphere. Self-consistency is achieved to within $1 \times 10^{-5} e/(a.u.)^3$ for charge and spin densities.

The MAE is obtained by applying the “local force” theorem for spin-quantization axis rotation in the (110) plane and using the Hellman–Feynman theorem to calculate a magnetic torque $T(\theta)$ (Ref. 8) at $\theta=\pi/4$ (where θ is the angle between the spin-quantization direction and the surface normal) with 400 special k points in the 1/4 of the 2D BZ.⁹ The use of magnetic torque allows us to calculate layer-resolved contributions to the total MAE. For comparison with earlier calculations, the calculated MAE (total and layer resolved) for Co/5Cu and Cu/Co/3Cu for the Cu(001) interlayer distance (3.415 a.u.) is shown in Table I. The results obtained are in fairly good agreement with our previous calculations⁷ based on the “local force” theorem for spin-quantization axis rotation, with results of relativistic screened Korringa–Kohn–Rostoker (KKR) calculations^{10,11} and with state-tracking calculations.¹²

The strain tensor for Co/5Cu and Cu/Co/3Cu is assumed³ diagonal with in-plane strain $e_0=e_{xx}=e_{yy}=(a_{Cu}-a_{Co})/a_{Co}$ and perpendicular strain $e_z=(l_{Co-Cu}-l_{Co-Co})/l_{Co-Co}$, where a and l are the lattice constant and interplanar distance, respectively. For a given in-plane strain, say $e_0=1.9\%$, the calculated ground-state relativistic total energy (E_{tot}) and MAE versus e_z are shown in Fig. 1 for Co/5Cu and in Fig. 2 for Cu/Co/3Cu.

For Co/5Cu the results indicate a good linear dependence of the MAE on e_z (cf., Fig. 1), in agreement with previous non-self-consistent SOC-second-variation calculations.¹³ As follows from the layer-by-layer “MAE” decomposition (cf., Fig. 1), the Co-layer contribution to the total MAE (e_z) is dominant compared with the Cu substrate contribution. For Cu/Co/3Cu the results again show that the MAE (e_z) (cf., Fig. 2) is well approximated by a linear dependence. The deviation from linearity is less than 0.05 meV and does not allow us to perform a rigorous quantitative treatment of nonlinear magnetoelastic effects. There is an increase in the absolute value of MAE with an increase of

TABLE I. The uniaxial surface MAE (meV/atom) for Co/5Cu and Cu/Co/3Cu (total and Co, Cu ML resolved) with the unrelaxed Cu(001) interlayer distance (3.415 a.u.) calculated by the magnetic torque method (T) in comparison with results of "local force" (LF) theorem for spin-quantization axis rotation and "state-tracking" (ST) method.

strain $|e_z|$ for the Cu/Co/3Cu case which is mainly due to the Co-layer contribution (cf., Fig. 2) while for Co/5Cu the absolute value of MAE decreases with an increase of $|e_z|$ (cf., Fig. 1). The Co-layer contributions to the MAE (e_z) for Co/5Cu and Cu/Co/3Cu are calculated to be dominant (cf., Figs. 1 and 2).

The uniaxial MAE of strained Co/5Cu and Cu/Co/3Cu is given by,³

$$E = -B_1^v(e_\perp - e_0) - \frac{B_1^s}{t}(e_\perp - e_0) + \frac{2K_2}{t}, \quad (1)$$

where B_1^v and B_1^s are volume and surface components of the magnetoelastic coupling coefficient,³ K_2 is the uniaxial surface magnetocrystalline anisotropy constant, and t is the magnetic layer thickness. Then, K_2 , volume (E_{ME}^v) and surface (E_{ME}^s) magnetoelastic energy contributions, and the total surface MAE (E^s) (cf., Table II) are calculated using the

FIG. 1. Ground-state all-electron total energy (left scale) and the MAE [total (circle), Co (square), Cu (diamond)] (right scale), as a function of perpendicular strain e_z for Co/5Cu.

FIG. 2. Ground-state all-electron total energy (left scale) and the MAE [total (circle), Co (square), Cu (diamond)] (right scale), as a function of perpendicular strain e_z for Cu/Co/3Cu.

MAE dependence on e_\perp , the equilibrium e_\perp (cf., Figs. 1 and 2), and the experimental value of B_1^v for fcc-Co (-1.12 meV/atom).¹⁴

As given in Table II for the total MAE there is fairly good agreement with the results of Ref. 15 for the Co/5Cu case and only qualitative agreement for the Cu/Co/3Cu case. The substantial disagreement between our results and those of Ref. 15 arises from the lack of a volume uniaxial MAE contribution in Ref. 15. As pointed out in Ref. 1, the absence of this contribution contrasts with the experimentally observed tetragonal distortion in Co films.

For the Cu/Co/3Cu we found MAE to be positive, in disagreement with the negative MAE measured in Ref. 16 for ultrathin Co/Cu(001) films (with more than 3 Co layers) covered by ten overlayers of Cu (cf., Table II). This dis-

agreement may be due to the recently demonstrated results¹¹ that there are strong oscillations in MAE (from positive to negative) for the unrelaxed Cu/Co/Cu(001) system as a function of the number of Co overlayers in the ultrathin film limit, and MAE is positive for one Co layer.

The surface magnetoelastic coefficients (cf., Table II) are calculated to be positive for both Co/5Cu and Cu/Co/3Cu and we found a surface magnetoelastic contribution to MAE from the Co layer to be significantly smaller for Cu/Co/3Cu than for Co/5Cu. Surprisingly, the surface magnetoelastic anisotropy estimated in Ref. 4 on the basis of the strain-dependent Néel model (0.07 meV/atom) and experimental data¹⁶ is in quite reasonable agreement with the result of our calculation (0.045 meV/atom). The magnetostriction coefficients, λ_{001} , were calculated by making use of magnetoelastic theory (with e_0 fixed by the substrate), and are -4.4×10^{-5} for Co/5Cu and 1.5×10^{-5} for Cu/Co/3Cu, respectively. Both of the calculated values of λ_{001} differ from the bulk value for fcc-Co [1.3×10^{-4} Ref. 14] due to surface contributions to magnetoelastic coupling coefficients.

Finally, in addition to the uniaxial surface MCA contribution [i.e., the $2K_2/t$ term in Eq. (1)], the magnetoelastic surface contribution to the uniaxial surface MAE has to be considered. The linear MAE dependence on perpendicular strain (e_z) (cf., Figs. 1 and 2) yields a qualitative similarity between first-principles theory and the phenomenological strain-dependent Néel model.⁴ The calculated values of the surface magnetoelastic coupling coefficient B_1^s for Co/Cu(001) and Cu/Co/Cu(001) are positive (cf., Table II) and cause the difference between ultrathin film effective magnetoelastic coefficient and its value for bulk fcc-Co.

Effects of heteroepitaxial strain on Laves phases TbFe_2 and DyFe_2

Department of Physics and Materials Research Laboratory, University of Illinois at Urbana-Champaign,
1110 West Green Street, Urbana, Illinois 61801

(110) oriented growth was observed for thin films of the highly magnetostrictive Laves phases TbFe_2 and DyFe_2 on Ta (110). On Nb (111), TbFe_2 nucleates in the (111) orientation. Depending on the substrate temperature during growth, varying degrees of residual tensile strain were observed in the films. For TbFe_2 grown on Ta (110) at 680 °C, x-ray diffraction revealed a splitting of the (220) Bragg reflection into a strain free component structurally coherent with the template, and a component with 0.5% biaxial tensile strain at room temperature. This strained component can be attributed to the difference in thermal expansion between the sapphire substrate and the TbFe_2 film. Magnetic hysteresis measurements revealed that the axis of easy magnetization lies in the film plane for both (110) and (111) oriented samples. © 1998 American Institute of Physics.

Cubic Laves phase compounds of the type RFe_2 (R: rare earth) offer several materials of interest in both applied and basic research. An example with possible applications is highly magnetostrictive TbFe_2 , epitaxially grown on a piezoelectric substrate, which holds promise for delay lines in surface acoustic wave devices.¹ These cubic compounds possess highly symmetric structures with 24 atoms in the conventional unit cell. Therefore they represent valuable model systems for the study of thin film growth applied to systems of moderate complexity. The ability to tailor specific aspects of the film properties, like the magnetic anisotropy by choice of specific growth conditions is the critical requirement for serious attempts to optimize these systems for specific applications.

Here we report investigations of the structural properties of thin epitaxial TbFe_2 and DyFe_2 films grown under various conditions and the influence of structure on their magnetic properties, with the main emphasis on TbFe_2 . The film growth was performed in a Perkin Elmer 430 molecular beam epitaxy (MBE) system with a base pressure of 6×10^{-11} Torr. Sapphire substrates in (11 $\bar{2}$ 0) *a*-plane or (0001) *c*-plane orientations were cleaned with basic and organic solvents and then annealed for one hour in vacuum at 1000 °C. Buffer layers of bcc refractory metals were then deposited by electron beam evaporation onto the heated substrates. Ta(110) was grown on the sapphire *a*-plane at 1000 °C, and Nb (111) was grown on *c*-plane sapphire at 750 °C. The growth rates were kept in the range 0.2 Å/s to 0.3 Å/s for a typical thickness of 400 Å. During this buffer layer growth the pressure increased to about 2×10^{-9} Torr.

The samples were next cooled to the range 450–680 °C for deposition of TbFe_2 or DyFe_2 at a growth rate of 0.2 Å/s for a film thickness of 400 Å to 1000 Å in a background pressure of about 8×10^{-11} Torr. TbFe_2 and DyFe_2 were grown in (110) orientation by using a Ta (110) buffer layer as template for nucleation of the desired orientation. On Nb (111), TbFe_2 nucleated in the (111) orientation. The Fe and

Tb were sublimed from high temperature effusion cells using high purity alumina and tantalum liners, respectively. With its higher vapor pressure, Dy allowed the use of a conventional effusion cell with BN liner. The Fe to Tb/Dy rate ratio was monitored using a quadrupole mass spectrometer and kept constant within $\pm 3\%$ of the nominal stoichiometry of 2:1. This mass spectrometer was calibrated by an independent measurement of film stoichiometry by Rutherford backscattering (RBS) with 2 MeV ^4He at an incidence of 15° with respect to the film normal. The film structure was investigated *in situ* by reflection high-energy electron diffraction (RHEED) and *ex situ* by x-ray diffraction on a two-circle diffractometer in the Bragg–Brentano geometry using Cu K_α radiation.

Oderno *et al.*² have shown that DyFe_2 and TbFe_2 (110) can be grown on Nb (110) buffer layers. In their work, the best results were obtained by preparing a 10–30 Å thick Fe seed layer, prior to the deposition of the Laves phase. The initial nucleation was described as three-dimensional suggested by RHEED investigations. Mosaicity could not be reduced below 1° for the (220) Bragg reflection.² Our RHEED investigations of the direct growth of DyFe_2 (110) on Ta (110) suggest two-dimensional nucleation, evolving into a rough three-dimensional surface after two to three monolayers and smooth again after a continuous film forms. Here we report that a mosaic spread as low as 0.04° could be observed without the use of an Fe seed layer. This corresponds to the resolution limit of the x-ray diffractometer and the line shape typically reflects the rocking curve of the Ta (110). The same results were obtained for TbFe_2 (110) samples, and is shown in Fig. 1(c). However, for TbFe_2 on Ta (110) the initial two-dimensional character of the film surface did not recover for films up to 1000 Å thick as evidenced by spot-like intensity enhancements superimposed on the observed RHEED streaks.

The crossover from the pseudomorphic two-dimensional to three-dimensional growth in the early nucleation stage most probably arises from the large lattice misfit (10%) between the Ta and Laves phase (110) surfaces, which causes

the critical strain state to be exceeded after less than three monolayers. This growth behavior was insensitive to the substrate temperature during growth. However, x-ray analysis revealed a clear dependence at room temperature of the residual tensile strain in the film plane on the growth temperature. Two effects were observed. First, with increasing growth temperature at $T > 600^\circ\text{C}$ the (220) TbFe_2 reflection

FIG. 2. (111) Bragg reflection and rocking curve (inset) of 400 Å thick TbFe_2 grown on Nb (111).

FIG. 3. Magnetic hysteresis of TbFe_2 films grown on (a) Ta (110) at 560°C , (b) Ta (110) at 680°C , and (c) Nb (111) at 520°C . All measurements were performed at room temperature.

splits into two components with a clear separation between two peaks for a film grown at 680°C [see Fig. 1(a)]. The low angle peak corresponds to a strain free film. The Ta (110) Bragg peak also suggests an essentially strain free template and the strong similarity of the rocking curves of the Ta (110) and TbFe_2 (220) reflection, both resolution limited, points clearly to the structural coherence between the buffer and the Laves phase epilayer. Second, the high angle component shifts towards increasing tensile strain in the film plane with higher growth temperature. The cause of the tensile strain may relate to the difference in the thermal expansion coefficients of sapphire and TbFe_2 since the large lattice misfit strain can be assumed to be compensated by disloca-

tion formation in the early stages of the film growth. The difference in thermal expansion can account for a tensile biaxial strain in the (110) plane of 0.5% at room temperature for a film grown at 680 °C.³ This is compatible with the observed 1% decrease of the d value for the (110) planes. The rocking curve width of this (220) component extends over several degrees. In order to create the observed strain-free Ta template and TbFe₂ epilayer at room temperature, the clamping effect of the substrate must be neutralized either by a compressive strain formed during growth or by a large increase of dislocations formed in the Ta buffer layer and part of the TbFe₂ film. In addition, the buffer layer partly alloyed with the Laves phase and RBS reveals a small interdiffusion in the interfacial region. This can also explain the observed saturation moment, which is only 70% of the expected magnetization of 800 emu/cm³ for TbFe₂ at room temperature,⁴ as evident in Fig. 3(b).

TbFe₂ (111) was grown on Nb (111). The very low surface free energy of the Nb (110) surface causes facets to form on the (111) Nb surface and results in a reduced structural quality of this template, compared to Ta (110) buffer layers. A strong tendency towards highly ordered TbFe₂ (111) phase formation was nevertheless observed. As shown in Fig. 2 the (111) reflection separates into a two-component line shape with a sharp Cu $K_{\alpha 1/\alpha 2}$ -split Bragg component on a broad background. The rocking curve of the sharp component is resolution-limited even though the Nb (222) rocking curve width is 0.41°. This suggests an intrinsic (111) growth preference for TbFe₂, which is corroborated by the fact that on Mo (110) and W (110), (111) growth was indeed observed.^{5,6}

Finally, we mention the results of magnetic measurements on these samples. Demagnetization effects were accounted for by calculating the effective field $H_{\text{eff}} = H - 4\pi N \cdot M$ with the demagnetization factor N equal to 0 and 1 for measurements with the applied field H in the plane and perpendicular to the plane of the films, respectively. As shown for TbFe₂ (110) and (111) in Fig. 3, the hysteresis curves suggest that the axis of easy magnetization lies in the film plane. Similar results were obtained for (110) DyFe₂ films on Ta (110). The qualitative characteristics of the hysteresis curves showed no temperature dependence in the range of 5 to 300 K. For an applied field in the film plane, the magnetization is reduced by coherent domain ro-

tation during reduction of the field from the saturated regime. At zero field the magnetization drops sharply followed by a step like feature. This magnetization characteristic probably arises from the magnetic anisotropy energy which favors the (111) axes of TbFe₂ bulk samples. Due to the form anisotropy the in-plane $[1\bar{1}1]$ direction of the TbFe₂ (110) plane or the $\langle 111 \rangle$ directions 20° off the film plane for TbFe₂ (111) are energetically preferred. Wang *et al.*,⁵ who observed a comparable magnetization drop for TbFe₂ (111) sputtered on W (110) buffer layers, suggest that the system has magnetic properties caused by interface reactions. They assumed a constant thickness of 10 nm for a soft magnetic material in the interfacial region causing a significant magnetization drop for thin films only. Our results do not support the same conclusion for films grown on Ta at low enough temperature to avoid interdiffusion. In these samples the saturation moments were close to the expected value of 800 emu/cm³ at room temperature and the magnetization drop occurred independent of the thickness of the films. Possible magnetic anisotropies in the film plane were not investigated.

Multilayers composed of alternate layers of iron-rare earth and Fe or FeCo alloys feature a high magnetostriction at low external fields and a coercive force as low as 5 mT. The coercive fields of as sputtered multilayers are significantly higher than that and the low values are attained after an anneal at 473 K. Since the hysteresis remaining after the heat treatment might be of magnetomechanical origin it is of interest to investigate the dynamic magnetomechanical characteristics of this class of multilayers. Experiments on multilayers of the composition (7 nm FeTb)/(8 nm/Fe) show a pronounced magnetomechanical damping maximum and an attendant decrease of Young's modulus upon annealing. Both occur in the vicinity of the coercive field. Their evolution as a function of the annealing and magnetic field will be described and it will be shown that they reflect an instability principally caused by the magnetomechanical interaction of the component layers of the multilayer. © 1998 American Institute of Physics.

[S0021-8979(98)40711-4]

INTRODUCTION

This article addresses instabilities in giant magnetostrictive, GMA, multilayers. GMA films have attracted attention in view of their potential applications as microactuators. Amorphous films of rare-earth metals can be prepared such that only the shape anisotropy remains.^{1,2} However, they display a low Curie temperature limiting their usefulness. Crystalline or microcrystalline GMA single-layer films have a higher Curie temperature but are characterized by a large coercive force which is equally detrimental. Nanocrystalline single layer GMA, finally, have a small coercive force but are to a large extent superparamagnetic.³ All desirable properties of GMA films, giant magnetostriction, high Curie temperature, large saturation magnetization, and low coercive force can be obtained by preparing suitable film composites and utilizing the multilayer concept developed in the late 1990s.⁴⁻⁷ The low coercive force may be understood to be a consequence of a rotational instability which might occur when, in response to an increasing external field the magnetically hard component of the multilayer, FeTb, suddenly adapts its orientation to the one of the magnetically soft components, Fe or FeCo. In GMA films a sizable strain accompanies the evolution of the magnetization. Therefore it must be expected that the magnetic instability is accompanied by an internal friction maximum. This article, then, reports on such an internal friction maximum which occurs at the steepest part of the magnetization curve and interprets it in terms of a magnetomechanical instability.

MODELING

It has been proposed that the large and sharp damping maximum at a critical field oriented perpendicularly to the

film surface occurring in amorphous Terfenol-D single-layer films is the signature of a magnetomechanical instability.⁸ The basis of the interpretation was a model free energy consisting of the sum of the magnetostatic, magnetoelastic, and elastic energies. A similar free energy may form the basis for the modeling of a magnetomechanical instability in a double layer, the elementary constituent of multilayers. Such a free energy will consist of three terms, the magnetoelastic, magnetostatic, and elastic energies. The magnetic properties of the multilayer can be understood in terms of the average magnetization and average magnetoelastic coupling constants of the component layers.⁷ Hence a model free energy, ϕ , is given by

$$\phi(\xi, \bar{\sigma}) = -(1 + \bar{\sigma})\cos^2(\xi) - h \sin(\xi) + \frac{1}{2}j\bar{\sigma}^2. \quad (1)$$

The energy ϕ , applied stress $\bar{\sigma}$, and the compliance j , are normalized as $\Phi/(\lambda\sigma_i)$, σ/σ_i , and $J\sigma_i/\lambda$. The normalized field is given by the parameter $h = M_s H/(\lambda\sigma_i)$. The quantities λ , σ_i , M_s , and J represent the average magnetostrictive strain, internal stress, saturation magnetization, and compliance. The quantity H is the external field. No demagnetization field has been included since only in-plane magnetization is considered.

The minimum of the energy (1) is located at $\xi_0, \bar{\sigma}_0$, which are solutions of $\partial\phi/\partial\xi = \partial\phi/\partial\bar{\sigma} = 0$. The quadratic expansion of the energy $\Delta\phi(\xi, \bar{\sigma}) = \phi(\xi, \bar{\sigma}) - \phi(\xi_0, \bar{\sigma}_0)$ around this minimum is given by

$$\begin{aligned} \Delta\phi(\xi, \bar{\sigma}) = & \frac{1}{2} \frac{\partial^2 \phi}{\partial \xi^2} (\xi - \xi_0)^2 + \frac{\partial^2 \phi}{\partial \xi \partial \bar{\sigma}} (\xi - \xi_0)(\bar{\sigma} - \bar{\sigma}_0) \\ & + \frac{1}{2} \frac{\partial^2 \phi}{\partial \bar{\sigma}^2} (\bar{\sigma} - \bar{\sigma}_0)^2. \end{aligned} \quad (2)$$

The cross term can be eliminated by the transformation

$$\Xi = (\xi - \xi_0)\cos(\theta) + (\bar{\sigma} - \bar{\sigma}_0)\sin(\theta),$$

^{a)}Summer intern from Ecole des Mines d'Als.

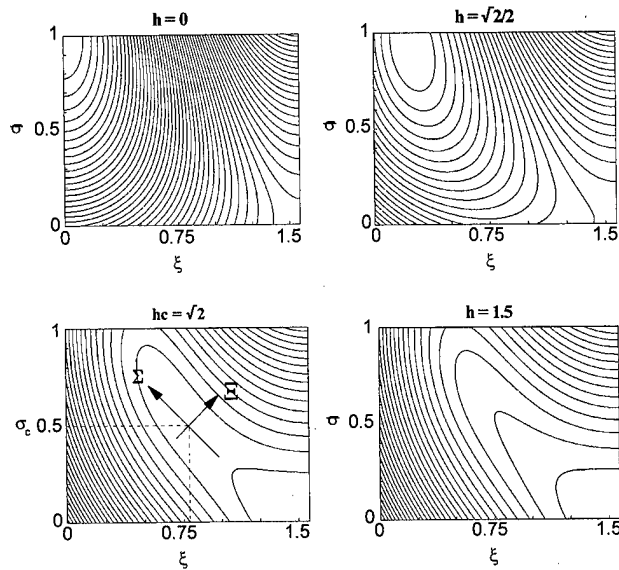

FIG. 1. Isopotential contours of the magnetomechanical potential (1) at four different values of the externally applied field h .

$$\Sigma = -(\xi - \xi_0)\sin(\theta) + (\bar{\sigma} - \bar{\sigma}_0)\cos(\theta),$$

where

$$\tan(2\theta) = \frac{2 \sin(2\xi_0)}{2(1 + \bar{\sigma}_0)\cos(2\xi_0) + h \sin(\xi_0) - j}.$$

The result of the transformation is the potential

$$\Delta\phi(\Xi, \Sigma) = \frac{\partial^2\phi}{\partial\Xi^2} \Xi^2 + \frac{\partial^2\phi}{\partial\Sigma^2} \Sigma^2, \quad (3)$$

in which the second derivatives $\partial^2\Delta\phi/\partial\Sigma^2$ and $\partial^2\Delta\phi/\partial\Xi^2$ represent the generalized magnetoelastic compliance and susceptibility. The generalized compliance becomes zero at a critical field h_c given by

$$h_c = \frac{\sin^2(2\xi_c) - 2j(1 + \bar{\sigma}_c)\cos(2\xi_c)}{j \sin(\xi_c)}, \quad (4)$$

in which equation the critical coordinates ξ_c and $\bar{\sigma}_c$ are

$$\sin(\xi_c) = \pm \sqrt{\frac{j+1}{3}}, \quad \bar{\sigma}_c = -\frac{j-2}{j},$$

$$h_c = \pm \frac{4(j+1)}{j} \sqrt{\frac{j+1}{3}}. \quad (5)$$

Isopotential lines for the potential (1) for $j=0.5$ are presented in Fig. 1 for various values of the field h . It can be seen from the figure that the two pairs ξ_0 , $\bar{\sigma}_0$ represent an extremum. At $h=h_c$ the potential displays a saddle point signaling an instability.

An expression for the internal friction as a function of the external field h can now be found. Physically, the internal friction, Q^{-1} , is the relative loss of mechanical energy, W , $\delta W/W$ per oscillatory cycle,⁹

$$2\pi Q^{-1} = \frac{\delta W}{W} = \frac{\oint \sigma d\epsilon}{1/2 J \sigma^2}. \quad (6)$$

FIG. 2. Experimental schematic.

Thus in terms of the generalized magnetoelastic compliance it may be written as

$$Q^{-1}(h) \propto \left[\frac{\partial^2 \Delta\phi}{\partial \Sigma^2}(h) \right]^{-1}. \quad (7)$$

It follows that in the linear approximation of Eq. (2) $Q^{-1}(h_c) \rightarrow \infty$, i.e., a sharp maximum of the internal friction will occur as the magnetization becomes unstable with respect to the applied field.

EXPERIMENTAL RESULTS

Multilayers of the configuration (7 nm FeTb)/(8 nm Fe) were sputtered¹⁰ on micromachined Si cantilevers. The dynamic mechanical properties of the composite Si/(7 nm FeTb)/(8 nm Fe) cantilever were determined as described before.¹¹ The sample configuration is also sketched in Fig. 2. The magnetic data were taken with a vibrating sample magnetometer (VSM). All data are room-temperature data. Annealing of the cantilevers was performed in high purity argon. Figures 3 and 4 contain the key experimental results. They show that the damping displays a maximum at the field where the change of the magnetization is greatest, approxi-

mately the coercive field which decreases as the annealing temperature increases. The damping maximum is more pronounced in the annealed samples showing a steeper change of the magnetization. It is proposed that both phenomena are a consequence of the observed changes of the state of stress¹² upon annealing.

DISCUSSION

Generally, domain wall nucleation and motion precedes rotation of the magnetization as saturation is approached, i.e., the transition from one poled state to its opposite re-

sembles a first-order transition whereas the formalism presented above applies only to a second-order transition. This apparent difficulty can be resolved by noting that, contrary to experiments determining $m(h)$, the present internal friction experiment determines the stress-induced change of the magnetization as a function of an external biasing field. Observations of the evolution of the domain structure in the investigated multilayers as a function of the externally applied magnetic and stress fields will further clarify this point.

Magnetostrictive multilayer films which combine exchange coupled giant magnetostrictive materials (amorphous $\text{Tb}_{0.4}\text{Fe}_{0.6}$) and soft magnetic materials with large polarizations and considerable magnetostriction (crystalline $\text{Fe}_{0.5}\text{Co}_{0.5}$) were prepared by magnetron sputtering. The microstructure and the magnetic properties of these multilayers were investigated as a function of the annealing temperatures and the corresponding film stresses. Giant magnetoelastic coupling coefficients (or magnetostrictions) are achieved at low fields, due to the magnetic polarization enhancement in such multilayers, the optimized stress state, and a suitable microstructure. For these optimized $\text{Tb}_{0.4}\text{Fe}_{0.6}$ (7 nm)/ $\text{Fe}_{0.5}\text{Co}_{0.5}$ (9 nm) multilayers a saturation magnetoelastic coupling coefficient of 27.5 MPa at 20 mT and a coercive field of 2 mT has been achieved. © 1998 American Institute of Physics. I. INTRODUCTION

Interest in giant magnetostrictive thin films has rapidly grown over the past few years due to their potential as powerful transducers for microactuators. Special features of magnetostrictive thin films in comparison to other smart materials in thin film form based on piezoelectric or shape memory effects are their remote control operation, their simple actuator layout, and low temperatures during fabrication being compatible to batch fabrication processes in the field of microelectronics and microelectromechanical systems (MEMS).

Research on these magnetostrictive materials concentrates on reducing the necessary driving magnetic fields. The most prominent approaches to date have been based on amorphous films of the system Tb-Dy-Fe-Co with a total rare-earth content of 33–45 at. %.¹

An alternative, very promising approach uses the combination of these amorphous giant magnetostrictive films and a nanocrystalline soft magnetic material with very high magnetic polarization in a multilayer arrangement. Giant magnetostriction at very low driving magnetic fields has been obtained for these multilayer materials, provided that the layers are thinner than the magnetic exchange length in order to be magnetically coupled. In this case the enhanced magnetization and the reduced anisotropy due to the soft magnetic, high polarization material introduced in the multilayer structure results in a decrease of the magnetic saturation field which is proportional to the ratio of the anisotropy and the saturation magnetization.² Using this approach, magnetoelastic coupling coefficients of 20 MPa at 20 mT for TbFe/Fe and of 28 MPa at 20 mT for TbFe/FeCo multilayers are obtained.³

In this paper, the effects of annealing processes and the individual layer thicknesses of $\text{Tb}_{0.4}\text{Fe}_{0.6}/\text{Fe}_{0.5}\text{Co}_{0.5}$ multilayers on the microstructure and the film stress are discussed in view of the corresponding magnetic and magnetostrictive

properties. The TbFe/FeCo multilayer system has been chosen for this study as amorphous TbFe exhibits the highest magnetostriction in amorphous single-layer films⁴ and FeCo combines both very high magnetization and high magnetoelastic coupling coefficients due to a saturation magnetostriction of $\lambda_s = 100 \times 10^{-6}$ and an effective Young's modulus of $E/(1 + \nu) = 200$ GPa.

II. EXPERIMENTAL DETAILS

The TbFe/FeCo multilayers were magnetron sputtered onto Si {100} substrates using a modified Leybold Z 550 device with composite-type targets (75 mm \varnothing) and a rotary turntable technique in a stop- and go-mode with no intentional substrate heating. The base pressure was $< 5 \times 10^{-5}$ Pa, the Ar sputtering pressure in all experiments was 0.4 Pa. The TbFe layers were dc magnetron sputtered

FIG. 1. High-resolution TEM micrograph from an as-deposited multilayer showing the amorphous structure of the TbFe layers and the long-range lattice fringe contrast in the FeCo layers.

FIG. 2. Magnetic polarization of $\text{Tb}_{0.4}\text{Fe}_{0.6}/\text{Fe}_{0.5}\text{Co}_{0.5}$ multilayers as a function of the layer thickness ratio. The comparison to the theoretical behavior for spring-magnet type multilayers assuming both parallel and antiparallel coupling reveals the antiparallel coupling of the films.

with a power of 150 W and an rf bias voltage of 220 V resulting in a deposition rate of 1.8 nm/s, while the FeCo films were deposited by rf magnetron sputtering with a power of 200 W and a deposition rate of 0.3 nm/s. These sputtering conditions lead to single-layer materials with in-plane magnetic easy axes. The polarization of the amorphous TbFe and the crystalline FeCo single layers were 0.35 and 2.3 T, respectively. Within this investigation the TbFe and FeCo layer thicknesses were varied between 2–15 and 1–25 nm, respectively. The total layer number was kept constant at 141, the first and the last layer being of FeCo: Auger electron spectroscopy (AES) depth profiling has shown that the upper FeCo layer works as a protective layer against oxidation.⁵

The microstructure of the films has been investigated by transmission electron microscopy (TEM) observation using a Jeol 3010 instrument. Specimens have been prepared in cross-section geometry by a combination of mechanical dimpling and ion-beam thinning. The film stresses were calculated by measuring the difference of the curvature of uncoated and coated Si {100} substrates using a laser interferometer. Young's modulus values for the multilayers were calculated from nanoindentation measurements at different loads which have been extrapolated to zero indenta-

Low-field magnetoelastic coupling coefficient for as-deposited and stress annealed (250 °C, 45 min) $\text{Tb}_{0.4}\text{Fe}_{0.6}$ (7 nm)/ $\text{Fe}_{0.5}\text{Co}_{0.5}$ (8 nm) multilayers in comparison to an amorphous, stress annealed (250 °C, 45 min) $\text{Tb}_{0.4}\text{Fe}_{0.6}$ single-layer film showing the significantly enhanced low-field magnetostriction especially for the stress annealed multilayer.

FIG. 4. Film stress for $\text{Tb}_{0.4}\text{Fe}_{0.6}$ (7 nm)/ $\text{Fe}_{0.5}\text{Co}_{0.5}$ (8 nm) multilayers as a function of the annealing temperature for an annealing time of 45 min and as a function of the annealing time for an annealing temperature of 250 °C (inset) showing the change of film stress from compressive to tensile state both with temperature and time.

tion depths in order to eliminate the substrate contribution.⁶ The magnetic properties were measured by vibrating sample magnetometry (VSM). The magnetostriction was characterized using the cantilevered substrate technique that allows the magnetoelastic coupling coefficient (b) to be determined from the bending of the substrate due to the magnetostriction (λ) in the film.⁷ The magnetoelastic coupling coefficient is defined by

$$b = \frac{-\lambda E_f}{1 + \nu_f},$$

with E_f and ν_f being the film's Young's modulus and Poisson ratio, respectively. The parameter b is, on one hand, a significant material-dependent parameter characterizing thin film bending actuators and, on the other hand, independent of the elastic data of the films.

FIG. 7. High-resolution TEM micrograph from a multilayer being annealed at 450 °C showing the absence of any amorphous phase TbFe.

III. RESULTS AND DISCUSSION

The TEM micrographs of the as-deposited samples show clearly the high degree of layer periodicity and, at high magnification, contrast from lattice fringes is evident (Fig. 1). Such contrast from the FeCo layers shows that the orientations of the grains are not random but, surprisingly, exhibit only a small number of variations and some of the layers contain crystallites with a lateral extent exceeding 100 μm while the normal extent is limited by the layer thickness. The TbFe layers are mainly amorphous, though isolated areas throughout the multilayer show lattice fringe contrast suggesting nanocrystallization or local oxidation, possibly initiated during the specimen preparation. At other isolated areas there is some evidence of contrast variations associated with the interfaces between the layers, which is thought to arise from local thickness variations produced by specimen preparation.

The saturation magnetic polarization, measured as a function of the layer thicknesses, reveals the antiparallel coupling of the layers by comparison with the theoretical behavior for exchange-coupled multilayers assuming both parallel and antiparallel coupling (Fig. 2). This antiparallel coupling reflects the strong interaction and therefore parallel coupling of the transition metals in both layers, which leads to an overall antiparallel coupling due to the stronger Tb moments in the ferrimagnetic TbFe layer. Furthermore, the magnetic data show that for FeCo/TbFe layer thickness ratios higher than 0.5, the total magnetic saturation polarization can be significantly enhanced compared to the single layer film.

Figure 3 exhibits not only the enhanced low field magnetostriction of $\text{Tb}_{0.4}\text{Fe}_{0.6}$ (7 nm)/ $\text{Fe}_{0.5}\text{Co}_{0.5}$ (9 nm) multilayers in comparison to an amorphous $\text{Tb}_{0.4}\text{Fe}_{0.6}$ single-layer film but reveals also the further enhancement in low field magnetostriction of multilayers being annealed at 280 °C in order to release compressive stresses. This multilayer shows a saturation magnetoelastic coupling coefficient of 27.5 MPa with a saturation and a coercive field of 20 and 2 mT, respectively. Compared to these values the magnetoelastic

coupling coefficient of a state-of-the-art amorphous TbFe single-layer film approaches only 10 MPa in an external field of 20 mT with a coercivity of the same magnitude. The as-deposited multilayers were found to be under compressive stress (approximately -300 MPa) leading to a perpendicular anisotropy while stress annealing at approximately 240 °C results in almost stress-free films and films being annealed at higher temperatures show tensile stress up to 700 MPa (Fig. 4). As a result of the altered stress state, annealing leads to an in-plane magnetic easy axis with reduced values for the magnetic saturation and coercive fields (Fig. 5) which are both determined by field-dependent magnetostriction measurements with the external field being applied parallel or perpendicular to the long axis of the cantilever, but always parallel to the film plane. While annealing at approximately 250 °C results in an optimum in terms of low field magnetoelastic behavior, the multilayers being annealed at higher temperatures show again higher values for coercive and saturation fields. This result can be explained by the microstructure of films, which in the case of an annealing temperature not higher than 250 °C (Fig. 6) shows only small changes, indicative of the onset of crystallization in the TbFe, compared to the as-deposited sample, while a multilayer being annealed at 450 °C reveals significant interdiffusion and total absence of any amorphous phase (Fig. 7).

Magnetic properties of amorphous Sm-Fe and Sm-Fe-B thin films fabricated by radio-frequency magnetron sputtering

Thin Film Technology Research Center, Korea Institute of Science and Technology, Seoul, Korea

Magnetic properties of giant magnetostrictive Sm-Fe and Sm-Fe-B thin films are systematically investigated over a wide composition range from 14.1 to 71.7 at. % Sm. The amount of B added ranges from 0.3 to 0.8 at. %. The microstructure mainly consists of an amorphous phase in the intermediate Sm content range from 20 to 45 at. %. Together with an amorphous phase, crystalline phases of Fe and Sm also exist at low and high ends of the Sm content, respectively. Well-developed in-plane anisotropy is formed over the whole composition range, except for the low Sm content below 15 at. % and the high Sm content above 55 at. %. As the Sm content increases, the saturation magnetization decreases linearly and the coercive force tends to increase, with the exception of the low Sm content where very large magnitudes of the saturation magnetization and the coercive force are observed due to the existence of the crystalline α -Fe phase. The coercive force is affected rather substantially by the B addition, resulting in lower values of the coercive force in the practically important Sm content range of 30–40 at. %. © 1998 American Institute of Physics.

[S0021-8979(98)25511-3]

Magnetic properties of amorphous Sm-Fe based alloys were previously investigated by many workers: for example, by Miyazaki and co-workers for thin films prepared by an evaporation method¹ and for melt-spun ribbons;² by Honda *et al.* for thin films fabricated by rf magnetron sputtering;³ more recently, by Seqqat *et al.* for thin films of Sm-Fe and Sm-Fe-B alloys and also for melt-spun ribbons of Sm-Fe-B alloys.⁴ Except for the results of Honda *et al.*,³ however, the previous investigations are more concerned about basic magnetic properties of rare-earth-Fe alloys rather than the improvement of the magnetic softness pertinent to practical applications of giant magnetostrictive materials. The present work is performed in a way similar to that of Honda *et al.*,³ but the effects of B are additionally examined and a more systematic investigation is carried out. The effects of B on magnetic and magnetostrictive properties of Tb-Fe based thin films were recently investigated by the present authors^{5,6} and it was found that B affects magnetic properties substantially and also improves the magnetostrictive characteristics of the thin films. The effects of B on magnetostriction and other magnetic properties of Sm-Fe based alloys were previously investigated for melt-spun ribbons produced by rapid quenching⁷ and amorphous bulks fabricated by high-speed sputtering.^{8,9} However, no attempts were made so far for Sm-Fe based thin films with the magnetostrictive applications in mind. It is noted that Sm-Fe-B thin films were previously fabricated by Seqqat *et al.*,⁴ but the investigated films are not pertinent to magnetostrictive applications, since the amount of B is very high (20 at. %) and the Sm content is below 26 at. %, being below the optimum composition of 30 at. % Sm.^{3,10}

Sm-Fe and Sm-Fe-B thin films with a thickness of about 1 μm were coated by rf magnetron sputtering on Si (100) substrates. A composite target consisting of an Fe disk (4 in. in diameter) and Sm chips was used. A pure Fe disk and an Fe (99.0 at. %)-B (1.0 at. %) disk were used to fabricate Sm-Fe and Sm-Fe-B thin films, respectively. Argon was used as the sputtering gas. The sputtering pressure was varied from 1 to 10 mTorr. The other sputtering conditions used in this work were: the base pressure of below 7×10^{-7} Torr, the target-to-substrate distance of 60 mm, and the rf input power of 300 W. The film thickness was measured by using a stylus-type surface profiler. The film composition of Sm and Fe was determined by electron-probe microanalysis. The amount of B was analyzed by spectrophotometry. The degree of crystallinity was observed by x-ray diffraction with Cu $K\alpha$ radiation. Magnetic properties were measured by using a vibrating sample magnetometer with a maximum magnetic field of 15 kOe.

In our experiments, widely ranged compositions were obtained by varying both the area fraction of Sm chips and the Ar gas pressure. More specifically, several experimental runs at various Ar gas pressures were carried out at a fixed target configuration and thin films with varying compositions were then obtained. Similar experimental runs were again conducted at different target configurations, producing thin films with varying compositions. The Sm content in the thin films fabricated at a fixed target configuration is found to increase with the Ar pressure. The present Ar gas dependence of composition is similar to that observed for Tb-Fe based thin films⁵ and may be explained by the difference in the scattering of sputtered Fe and Sm particles.

All the fabricated films were checked by x-ray diffraction to examine the degree of crystallinity, and some of the diffraction results are shown in Fig. 1 for the Sm-Fe system

^{a)}Electronic mail: mmlshl@kistmail.kist.re.kr

FIG. 1. The variation of x-ray diffraction patterns with Sm content for the Sm-Fe system.

over a wide composition range. The results for the Sm-Fe-B system are similar to those for the Sm-Fe system. The peaks at $2\theta = 33^\circ$ and 70° are from the Si substrate. Sharp crystalline peaks of α -Fe are clearly seen at low Sm content below ~ 20 at. %. The α -Fe peaks are slightly shifted toward a lower diffraction angle indicating a lattice expansion of the α -Fe phase. The α -Fe crystalline peaks disappear and a broad peak characteristic of an amorphous phase emerges as the Sm content exceeds ~ 20 at. %. It is of interest to note that the position of the broad maximum (in 2θ) shifts toward the lower diffraction angle as the Sm content increases. This is clearly seen for the films of $\text{Sm}_{24.0}\text{Fe}_{76.0}$ and $\text{Sm}_{34.1}\text{Fe}_{65.9}$ where broad maxima occur at $2\theta = 41^\circ$ and 35° , respectively. At a Sm content higher than 45 at. %, the microstructure consists of a mixture of an amorphous phase and the α -Sm phase. The relatively large peak below $2\theta = 30^\circ$ observed in some samples is thought to be related to a Sm oxide, possibly Sm_2O_3 .

The direction of easy magnetization is known to be an important factor for the magnetic softness of R-Fe thin films,^{5,6,11} and hence, the change in anisotropy is investigated as a function of the composition. The distribution of magnetic anisotropy is investigated by examining hysteresis loops measured in the in-plane and the direction perpendicular to the film plane. Some results for these hysteresis loops are shown in Figs. 2(a)–2(d). Corrections with regard to demagnetizing fields are not made, so the loops shown in the figures are more squared than the “true” ones and, due to a larger demagnetizing field for a perpendicular loop, the degree of squareness of a perpendicular loop is expected to be larger. For the films with a similar Sm content, no noticeable difference in the direction of easy magnetization is observed with the addition of B, except for the films with low Sm

FIG. 2. The variation of the shape of M - H hysteresis with Sm content for alloys of (a) $\text{Sm}_{15.2}\text{Fe}_{84.0}\text{B}_{0.8}$, (b) $\text{Sm}_{25.8}\text{Fe}_{73.5}\text{B}_{0.7}$, (c) $\text{Sm}_{36.9}\text{Fe}_{62.5}\text{B}_{0.6}$, and (d) $\text{Sm}_{68.4}\text{Fe}_{31.3}\text{B}_{0.3}$. Two hysteresis loops are shown for each sample, one measured by applying magnetic fields in the in-plane direction and the other in the perpendicular direction.

content where the α -Fe phase exists. In this low Sm content range, both B-free and B containing films exhibit in-plane anisotropy but better in-plane anisotropy is observed for B added films. Also, at this low Sm content, the shape of hysteresis loops measured in the in-plane direction is inclined substantially. This is indicated by low magnitudes (below 0.1) of the remanence ratio, the results of which are shown in Fig. 3(a) as a function of the composition. The remanence ratio is defined as M_r/M_{15} , where M_r is the remanent magnetization and M_{15} the magnetization at 15 kOe. In the composition range from 20 to 55 at. % Sm, well-developed in-plane anisotropy is formed and hysteresis loops are highly squared with the remanence ratio of most thin films being greater than 0.6 [Fig. 3(a)]. No substantial anisotropy is observed at a Sm content higher than 55 at. %; no substantial difference being noted in the shape of hysteresis loops measured in the in-plane and perpendicular directions. Intermediate magnitudes of the remanence ratio (0.29–0.40) are seen at this high Sm content. Anisotropy is little affected by the B addition and this behavior is in contrast with that observed in Tb-Fe based thin films where anisotropy is greatly influenced by the presence of B.⁵ Ferromagnetic behavior is observed to exist in the present Sm content range (up to 71.7 at. %). This behavior is to be compared with that observed in Tb-Fe based thin films where superparamagnetic behavior appears as the rare-earth content exceeds ~ 66 at. %.⁵

The results for M_{15} and the coercive force are shown, respectively, in Figs. 3(b) and 3(c) as a function of the composition. Since most of the present thin films saturate at a magnetic field well below 15 kOe, M_{15} is practically identical to the saturation magnetization. The coercive force (H_c) is obtained by applying the maximum magnetic field of 15

FIG. 3. The value of (a) the remanence ratio (M_r/M_{15}), (b) saturation magnetization (M_{15}), and (c) coercive force (H_c) as a function of Sm content. The results of Sm-Fe thin films are indicated by filled circles and those of Sm-Fe-B thin films by unfilled circles. In the case of H_c , the results of Honda *et al.* (Ref. 3) for Sm-Fe thin films (indicated by triangles) are also shown for comparison.

kOe. The results are obtained from the hysteresis loops measured in the in-plane direction. In the case of the coercive force, the results of Honda *et al.*³ obtained for Sm-Fe thin films are also shown in Fig. 3(c) for comparison.

Except for very low Sm content where the α -Fe phase exists, the saturation magnetization decreases nearly linearly from 8950 to 1580 G as the Sm content increases from 14.1 to 71.7 at. %. Again, no substantial difference in the saturation magnetization is seen with the B addition and this is compared with relatively large reduction in Tb-Fe based thin films by the B addition.⁵ As can be expected from the ferromagnetic coupling between Sm and Fe (note that Sm is a light rare-earth element), no compensation composition is observed. The linear dependence of the magnetization may indicate that the total magnetization of the alloy is simply an arithmetic sum of Fe and Sm elements, the magnetic moment of Fe being larger than that of Sm.⁴ Of course, the relation of the arithmetic sum will hold only in the composition range where no paramagnetic α -Sm precipitates exist. It is estimated from the extrapolation of the present data that the magnetization reaches zero at ~ 85 at. % Sm. The extraordinarily large magnitude of M_{15} at the low end of the Sm content is due to the formation of the α -Fe phase with a large magnetic moment.

The magnitude of H_c is large for the thin films with the α -Fe phase, but, with the disappearance of the crystalline phase, the value of H_c is reduced significantly to 10 Oe. This may be because intrinsic magnetocrystalline anisotropy is effectively reduced by the formation of an amorphous phase. The value of H_c tends to increase with increasing Sm content. This can be expected from the larger anisotropy of Sm than that of the Fe element. It may be noted, however that in the case of binary Sm-Fe thin films, a closer examination shows a tendency of a broad maximum in the H_c -Sm content plots at a Sm content of 40 at. % when the data of the thin films with well-developed in-plane anisotropy are taken into account. A similar result was previously reported by Miyazaki *et al.* for melt-spun Sm-Fe ribbons.² The coercive force of Sm-Fe thin films was also investigated by Honda *et al.*³ but with a paucity of data and a large data scattering at the Sm content of 50 at. %, the tendency of the coercive force as a function of the composition cannot be drawn. Unlike the other magnetic properties, the coercive force is affected rather substantially by the addition of B; the H_c -Sm content plot is shifted toward higher Sm content with the B addition. This results in lower values of the coercive force of B containing thin films in the practically important Sm content range of 30–40 at. % where optimum magnetostrictive characteristics are observed.^{3,10} Since the coercive force is closely related to magnetostrictive characteristics at low magnetic fields, low-field magnetostrictive characteristics are improved by the addition of B.¹⁰ As can be seen in Fig. 3(c), at a Sm content below 40 at. %, the present values of H_c of the Sm-Fe thin films are in fair agreement with those reported by Honda *et al.*³ At a Sm content higher than 40 at. %, however, our values are lower than the reported ones. Magnetostrictive properties of the present thin films are found to be very good, particularly at low magnetic fields, and these magnetostrictive results will be published elsewhere.¹⁰

Application of the ratio $\Delta\lambda/\Delta M$ to giant magnetostrictive materials in the $\langle 110 \rangle$ easy regime

S. C. Busbridge and A. R. Piercy

Department of Mechanical and Manufacturing Engineering, University of Brighton, Brighton BN2 4GJ, United Kingdom

The parameter $\Delta\lambda/\Delta M$ is a useful tool for investigating the magnetization process in magnetostrictive materials. This work extends the use of this parameter from that previously explored in the $\langle 100 \rangle$ and $\langle 111 \rangle$ easy regimes to the $\langle 110 \rangle$ easy regime. Theoretical values of $\Delta\lambda/\Delta M$ are presented for all possible domain wall motions that produce an increase in magnetization. In the $\langle 110 \rangle$ easy regime, $\Delta\lambda/\Delta M$ has contributions from both λ_{100} and λ_{111} , but for practical purposes it is only necessary to consider the latter for the C15 phase giant magnetostrictive materials, because $\lambda_{111} \gg \lambda_{100}$. Under such conditions there are 61 different wall motions but only four (nonzero) values for $\Delta\lambda/\Delta M$. We have obtained the theoretically generated magnetostrain versus magnetization curve, derived from a model of distinct domain wall motions with successively higher values of $\Delta\lambda/\Delta M$. It is shown that this curve is a good fit to the experimental magnetostrain versus magnetization curve obtained for $\text{Tb}_{0.1}\text{Ho}_{0.9}\text{Fe}_{1.9}$, measured at intervals over the temperature range 213–373 K. Since it is known that equivalent theoretical curves in the $\langle 100 \rangle$ and $\langle 111 \rangle$ easy regimes model the magnetization process well, and that $\text{Tb}_x\text{Ho}_{1-x}\text{Fe}_{1.9}$ ($0 < x < 0.2$) undergoes a spin reorientation from $\langle 111 \rangle$ to $\langle 110 \rangle$ at approximately 260 K, and then to $\langle 100 \rangle$ as the temperature is reduced further, we conclude that $\Delta\lambda/\Delta M$ may be used in the $\langle 110 \rangle$ easy regime. However, the large number of wall motions makes it more difficult to identify any particular motion. © 1998 American Institute of Physics. [S0021-8979(98)40911-3]

INTRODUCTION

The ratio of the change in magnetostriction to the change in magnetization, $\Delta\lambda/\Delta M$ is a useful parameter with which to probe the magnetization process in magnetostrictive materials. An understanding of the magnetization process is important to the further improvement of device grade material.^{1,2} This article extends the use of this parameter from that previously explored in the $\langle 100 \rangle$ and $\langle 111 \rangle$ easy regimes³ to the $\langle 110 \rangle$ easy regime.

The $\langle 110 \rangle$ easy regime is relatively unusual, but it does occur under certain conditions in the $\text{Ra}_x\text{Rb}_{1-x}\text{Fe}_2$ (Ra, Rb=rare-earth elements) system.⁴ Under such conditions, the usual two-term anisotropy model is adequate provided that $-\frac{4}{9}K_1 < K_2 < 0$.

THEORETICAL BASIS FOR $\Delta\lambda/\Delta M$

A domain wall moving through a volume fraction f of the sample will give rise to a change in magnetization ΔM :

$$\Delta M = fM_s(\cos \theta_2 - \cos \theta_1), \quad (1)$$

where M_s is the saturation magnetization and θ_2 and θ_1 are the directions of the magnetization in each domain either side of the moving wall with respect to the measurement direction 0. Thus

$$\cos \theta_2 = (l_2 l_0 + m_2 m_0 + n_2 n_0) \quad (2)$$

and similarly for $\cos \theta_1$, where l , m , and n are the direction cosines. The change in strain $\Delta\lambda$ is given by

$$\Delta\lambda = f(\lambda_{2,0} - \lambda_{1,0}), \quad (3)$$

where $\lambda_{2,0}$ and $\lambda_{1,0}$ are the magnetostrains measured in direction 0 when the magnetization lies in directions 2 and 1, respectively. Hence

$$\lambda_{2,0} = \left(\frac{3\lambda_{100}}{2} \right) \left(l_2^2 l_0^2 + m_2^2 m_0^2 + n_2^2 n_0^2 - \frac{1}{3} \right) + 3\lambda_{111}(l_2 m_2 l_0 m_0 + m_2 n_2 m_0 n_0 + n_2 l_2 n_0 l_0) \quad (4)$$

and similarly for $\lambda_{1,0}$. The normalized value of $\Delta\lambda/\Delta M$ is therefore intrinsic to the magnetization process in that it is dependent only on the change of direction of the magnetization and the resultant change in strain. In the case of domain wall motion, $\Delta\lambda/\Delta M$ will take a unique value, for each type of wall motion, in terms of the ratios of the constants λ_{111}/M_s and λ_{100}/M_s . For the $\langle 111 \rangle$ easy regime the contribution of λ_{100}/M_s to $\Delta\lambda/\Delta M$ is always zero, and for the $\langle 100 \rangle$ regime the contribution of λ_{111}/M_s to $\Delta\lambda/\Delta M$ is always zero. In the $\langle 110 \rangle$ easy regime, the value of $\Delta\lambda/\Delta M$ will, in general, consist of contributions from both λ_{111}/M_s and λ_{100}/M_s . In the case of magnetic rotation, $\Delta\lambda/\Delta M$ will generally be a function of M and depend on the direction of rotation of M_s , again with contributions from both λ_{111}/M_s and λ_{100}/M_s . When considering dynamic changes in magnetization⁵ the equivalent parameter is d/χ , because $d = \Delta\lambda/\Delta H$ and $\chi = \Delta M/\Delta H$. We have previously shown that the quasistatic and dynamic magnetization processes are likely to be the same in the $\langle 111 \rangle$ and $\langle 100 \rangle$ regimes.⁶ A more detailed comparison of $\Delta\lambda/\Delta M$ and d/χ as functions of M/M_s suggests that this conclusion also holds true in the $\langle 110 \rangle$ easy regime.

TABLE I. Values of $\Delta\lambda/\Delta M = A(\lambda_{100}/M_s) + B(\lambda_{111}/M_s)$ for all possible wall motions in the $\langle 110 \rangle$ easy regime.

When considering the possible values for $\Delta\lambda/\Delta M$, it is only necessary to consider those magnetization processes that give rise to a positive value for ΔM . Most of the values for $\Delta\lambda/\Delta M$ so generated are positive (for positive magnetostriction constants), although negative values are also generated. Experimental evidence suggests that negative values of $\Delta\lambda/\Delta M$ are not generally observed. A negative value of $\Delta\lambda/\Delta M$ would require a decrease in magnetostriction to accompany an increase in magnetization. Although this is possible (the magnetostriction is an even power function of the magnetization) it appears not to be energetically favorable. In essence the magnetization drives the magnetostriction with increases in the value of $\cos \phi$ (ϕ being the angle between M_s and H) being magnetostatically inefficient.

In the $\langle 100 \rangle$ easy regime the possible values for $\Delta\lambda/\Delta M$ are (in units of λ_{100}/M_s) 0, 0.612, and 1.837. A value of -0.612 is also possible. In the $\langle 111 \rangle$ easy regime the possible values are (in units of λ_{111}/M_s) 0, 0.707, 1.414, and 2.123. Negative values for each of these are also possible. In the $\langle 110 \rangle$ easy regime there is a total of 132 possible different wall motions (12 are 180°, 48 are 120°, 24 are 90°, and 48 are 60°) and of these, 61 give rise to a positive value for

ΔM . The corresponding different values for $\Delta\lambda/\Delta M = A(\lambda_{100}/M_s) + B(\lambda_{111}/M_s)$ are given in Table I, together with the type and equivalent number of wall motions. In all cases it is assumed that the measurement and magnetization directions are $[112]$.

Although there is a large number of different wall motions, for practical purposes it is only necessary to consider the values of B for the giant magnetostrictive rare-earth iron materials, since $\lambda_{111} \gg \lambda_{100}$ (even though this may be true, it is necessary to consider λ_{100} in the $\langle 100 \rangle$ easy regime, because the contribution to $\Delta\lambda/\Delta M$ from λ_{111}/M_s is always zero). There are therefore only five different non-negative values of $\delta\lambda/\Delta M$ (0, 0.173, 0.866, 1.732, and 2.598).

According to torque measurements made by Koon *et al.* on single crystals, $\text{Tb}_x\text{Ho}_{1-x}\text{Fe}_2$ ($0 < x < 0.20$) undergoes a spin re-orientation from $\langle 111 \rangle$ to $\langle 110 \rangle$ just below room temperature as the composition is made more Ho rich.⁷ When $x=0.1$ the spin reorientation is close to 260 K. Cooling below this temperature and/or a reduction in the value of x brings about a gradual shift in the easy direction of magnetization towards $\langle 100 \rangle$.

Figure 1 shows normalized magnetostrain versus magne-

FIG. 1. Normalized strain versus normalized magnetization for $\text{Tb}_x\text{Ho}_{1-x}\text{Fe}_{1.9}$. The points are experimental data and the lines are theoretically derived from $\Delta\lambda/\Delta M$. For each easy axis regime the strain has been normalized to the appropriate value of λ_{111} .

tization measurements for $\text{Tb}_x\text{Ho}_{1-x}\text{Fe}_{1.9}$ ($x=0, 0.1$, and 0.2) obtained at a temperature of 260 K. The magnetostrain was measured with a strain gauge and the magnetization by a two-coil induction technique. Similar curves are obtained for $x=0.1$ over the temperature range 170–370 K. The solid lines represent possible theoretical magnetization processes for the $\langle 100 \rangle$, $\langle 110 \rangle$, and $\langle 111 \rangle$ easy regimes obtained from values of $\Delta\lambda/\Delta M$. In all three regimes the initial demagnetized state is assumed to be one in which all equivalent easy directions are equally populated. The magnetization is postulated to proceed by domain wall motions with the lowest possible values of $\Delta\lambda/\Delta M$, each process being completely exhausted before moving onto wall motions with successively higher values of $\Delta\lambda/\Delta M$. The total magnetization and total strain are treated as cumulative summations of the contributions from the individual wall motions. Rotation must be included to describe the final approach to saturation.

The theoretical curves follow the general change in shape of the experimental curves, as the direction of the easy axis is varied. This substantiates a correlation between the observed strain versus magnetization curve and the theoretical plot predicted from the values of $\Delta\lambda/\Delta M$ in each of the easy axis regimes. It should be noted, however, that the results from torque measurements and from Mossbauer studies do not entirely agree with each other in the transition region, and that the alternative transition from $\langle 111 \rangle$ to $\langle 100 \rangle$ via $\langle 1uu \rangle$ ($0 < u < 1$) proposed by Altzmony and Dariel⁸ is also well described by the theoretical magnetization processes shown in Fig. 1.

DISCUSSION

The parameter $\Delta\lambda/\Delta M$ is a useful tool for investigating the magnetization process in magnetostrictive materials, and gives a good fit to experimentally obtained data in the $\langle 100 \rangle$ and $\langle 111 \rangle$ easy regimes.

However, in the $\langle 110 \rangle$ easy regime the method has become insensitive to the precise direction of the easy axis, because the large number of possible wall motions permits a greater number of plausible theoretical magnetostriction versus magnetization curves to be postulated. Unless it is possible to identify a single domain wall motion process, it will always be possible to find more than one theoretical magnetization process to fit a given set of experimental data.

Magnetostriction and susceptibilities of twinned single crystals of Terfenol-D

X. G. Zhao^{a)} and D. G. Lord

Joule Laboratory, Department of Physics, University of Salford, Salford M5 4WT, United Kingdom

Measurements are presented of the dc magnetostriction, and both the ac and dc susceptibility along the three orthogonal axes of $[11\bar{2}]$, $[111]$, and $[1\bar{1}0]$ from twinned single crystals of Terfenol-D as a function of varying compressive stress and magnetic field mutually applied along the $[11\bar{2}]$ rod axis. The data are used in an attempt to analyze the magnetization processes occurring in such a specimen. The experimental results show clearly the two characteristics of the magnetization process corresponding to (i) the magnetostrictive “jump” effect, and (ii) the slow changes of magnetostriction occurring above the “jump.” It is estimated that in stage (i) of the magnetization process, the domains aligned along the $[111]$ axis by the applied stress rapidly and massively redistribute their moments both to the $[111]$ direction closest to the applied field as well as to the $[\bar{1}\bar{1}\bar{1}]$ and $[1\bar{1}\bar{1}]$ directions; and during stage (ii), the domains occupying the $[\bar{1}\bar{1}\bar{1}]$ and $[1\bar{1}\bar{1}]$ directions redistribute to the $[111]$ successively by non- 180° domain-wall motion. However, two fine magnetization processes are found in the field range of the jump effect indicating that some domains must redistribute from the $[111]$ to the $[\bar{1}\bar{1}\bar{1}]$ and $[1\bar{1}\bar{1}]$ initially, then to the $[111]$ even when the field is only increased in the initial stage (i). The nonzero susceptibilities measured along the $[111]$ and $[1\bar{1}0]$ suggest that both the volumes of parent and twin material as well as the probabilities for domain redistribution from one easy direction to the $[\bar{1}\bar{1}\bar{1}]$ and $[1\bar{1}\bar{1}]$ might be different. © 1998 American Institute of Physics. I. INTRODUCTION

Giant magnetostrictive $\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2$, known as Terfenol-D, is of significant interest technologically for actuator and transducer applications. Commercially available material, grown by a free-standing zone (FSZ) technique, is normally composed of dendritic plates which often contain single or multiple crystallographic twins with a common (111) plane. Such materials exhibit significant magnetoelastic strain,^{1,2} the evolution of which is characterized by discontinuous strain changes, known as “jump” or “burst” effects, which occur at particular values of applied field. It was initially thought such jumps were the result of magnetization rotation from other easy directions to that closest to the applied field. However, numerous experimental investigations by Teter *et al.*³ and other authors^{4–9} have shown the dendritic and twin structure of Terfenol-D make the magnetization process much more complicated, and infer that there must be various processes involved, including domain-wall movement, and not only the one domain rotation process.

In this paper, measurements of the dc magnetostriction, and both the ac and dc susceptibility along the three orthogonal axes of $[11\bar{2}]$, $[111]$, and $[1\bar{1}0]$ (as shown in Fig. 1) are presented from twinned single crystals of Terfenol-D as a function of varying compressive stress and magnetic field mutually applied along the $[11\bar{2}]$ rod axis. The data are used in an attempt to analyze the magnetization processes occurring in such a specimen.

II. EXPERIMENTAL DETAILS

Samples of 54 mm in length along the $[11\bar{2}]$ growth direction were obtained from 7.7 mm diam rods prepared by Edge Technologies, Inc. by a FSZ technique, and were metallographically checked to be twinned single crystals. Each rod was supported in an assembly containing three pairs of mutually orthogonal pick-up coils. Differential magnetic susceptibility data were obtained by subjecting the rod specimens to a dc and superimposed ac magnetic field directed along the $[11\bar{2}]$ rod axis. The ac ripple field, of frequency 77 Hz and of 4 Oe in amplitude, was held constant while a lock-in amplifier was used to detect the signals induced in the coils. The magnetization along the $[11\bar{2}]$ was determined by a flux meter. Magnetostriction measurements were made

FIG. 2. The field dependencies of (a) $\lambda[112]$, (b) $\lambda[110]$, and (c) $M[112]$ for different values of applied stress.

using standard strain gauge techniques. The compressive stress was applied to the ends of the rod by a pair of modified electromagnet pole pieces, in one of which a piston could be driven by compressed air. All measurements were carried out at ambient temperature and with closed magnetic circuits. For all the data described here, the applied field was swept from +8000 to -8000 Oe.

III. RESULTS AND DISCUSSION

The field dependencies of magnetostrictions along the $[112]$ and $[110]$ directions and magnetization along the $[112]$, named $\lambda[112]$, $\lambda[110]$, and $M[112]$, respectively, are shown in Fig. 2 for different values of applied stress. With zero stress applied, the material shows a small saturation value of $\lambda[112]$ of about 750×10^{-6} . It is clear from considering $\lambda[112]$ and $M[112]$ that 180° domain-wall motions dominate the magnetization process near zero field. However, when a 10 MPa compressive stress is applied to the specimen, a "jump" effect occurs at a particular field, the "jump" field, of about 250 Oe. When this initial "jump" is completed, the measured magnetostrictions reach relatively high values of about 1100×10^{-6} for $\lambda[112]$ and 800×10^{-6} for $\lambda[110]$. Further increases in applied field result in the magnetostrictions changing slowly in a manner analogous to that pertaining to the zero stress situation. When the applied stress is increased further, there is only a small influence on the saturation value of $\lambda[112]$, but the "jump" field increases to higher values. The curves seem to be shifted to the higher fields as a whole, especially for the portion associated with the slow variations occurring above the "jump" field. This characteristic of the slow change in magnetostriction towards saturation has been observed in all available twinned crystals of Terfenol-D.

It is reasonable to suppose that the magnetization process can be simply divided into two stages which correspond to (i) the magnetostrictive "jump" effect, and to (ii) the slow changes of magnetostriction occurring above the "jump."

FIG. 3. The field dependency of the ac susceptibilities $\chi[112]$, $\chi[111]$, and $\chi[110]$ as well as that of quasistatic d_{33} , for different values of applied stress: (a) zero and (b) 10 MPa.

Referring to Fig. 1, the experimental results indicate that in stage (i) of the magnetization process, the domains aligned along the $[111]$ axis by the applied stress rapidly and massively redistribute their moments both to the $[111]$ direction that is closest to the applied field as well as to the $[1\bar{1}\bar{1}]$ and $[11\bar{1}]$ directions. During stage (ii), the domains having magnetizations occupying the $[11\bar{1}]$ and $[1\bar{1}\bar{1}]$ directions redistribute their moments to the $[111]$ successively by non- 180° domain-wall motion. The large demagnetization factor along the $[111]$ axis, resulting from the platelike microstructure of the twinned crystals, is thought to be responsible for the characteristic strain behavior exhibited in this second stage of the magnetization process.¹⁰

The field dependency of the ac susceptibilities $\chi[112]$, $\chi[111]$, and $\chi[110]$, as well as that of quasistatic d_{33} ($d\lambda[112]/dH$), are shown in Fig. 3(a) for the zero-stress situation. Consistent with the slow change of magnetostriction, d_{33} and $\chi[112]$ illustrate almost linear changes with applied field between zero and 2500 Oe. However, more complicated variations are exhibited in the field behavior of both $\chi[111]$ and $\chi[110]$. When the field is decreased from positive saturation to zero, $\chi[110]$ decreases from its saturation value, reaches a negative maximum at an applied field of 1500 Oe, then increases until zero field. At the same time, $\chi[111]$ keeps almost unchanged until the field reduces to 1500 Oe, then it linearly increases until the field reduces down to zero.

Figure 3(b) shows the influence of a 10 MPa applied stress on the change of d_{33} and the susceptibilities. Some peaks appear in the field range between ± 250 Oe that corresponds to stage (i) of the magnetization process. Beyond this field range, all the variations behave like those in the unstressed case. The peak maximum in $\chi[112]$ and the peak minima in $\chi[111]$ and $\chi[110]$ are located at the same field value, but this value is lower than that associated with the peak in d_{33} . This situation is found for both positive and negative applied fields and would suggest that, at these low fields, 180° domain-wall motion is occurring, which yields zero contribution to the magnetostriction.

With reference to Fig. 1 depicting the projections from, say, a parent crystal plate, it can be seen that $\chi[110]$ results

FIG. 4. The field dependencies of the quasistatic (dc) susceptibility and d_{33} along the $[11\bar{2}]$ direction for different values of applied stress: (a) 10, (b) 20, (c) 30, and (d) 40 MPa.

from the competition between the magnetization contributions from along the $[\bar{1}11]$ and $[11\bar{1}]$ axes. Similarly, $\chi[111]$ is from the competition between the magnetization contributions along the $[111]$ and the $[\bar{1}11]$, $[\bar{1}\bar{1}1]$, $[\bar{1}1\bar{1}]$, and $[11\bar{1}]$. If (a) the volumes of parent and twin plates in such a twinned single crystal were equal, and (b) the probabilities for a domain rotating its moment from $[111]$ to $[\bar{1}11]$ and $[11\bar{1}]$ were equal, too, no matter where this domain was located, then the $\chi[111]$ and $\chi[1\bar{1}0]$ should remain zero during both these two stages of the magnetization process. However, this has not been found to be the case in any of our susceptibility measurements and would suggest the existence of differences in both volume fraction and domain occupation probability.

The quasistatic (dc) susceptibility and d_{33} along the $[11\bar{2}]$ direction were obtained by differentiating the experimental data of magnetization and magnetostriction variations with field and are shown in Fig. 4. Two peaks can be distinguished in the field variations from both of these parameters in the field range of the stage (i) jump effect. The two peaks in d_{33} appear to be almost the same in amplitude whereas in the susceptibility, the higher-field peak appears as a shoulder on the more prominent lower-field peak. A sharp peak in dc susceptibility is also evident near zero field, even when the stress is applied, indicating the existence of 180° domain-wall motion in all cases. It is interesting to note that this peak is not evident from the nonzero stress data obtained from ac susceptibility measurements; this may be due to the higher magnetic hysteresis in this case.

In Fig. 5 the field variation of the ratio d_{33}/χ , experimentally determined from the quasistatic data, is shown for

FIG. 5. The field variation of the ratio d_{33}/χ along the $[11\bar{2}]$, experimentally determined from the quasistatic data, for various applied stresses.

various applied stresses. A peak, with an amplitude of about 1.75 clearly appears in the stage (i) jump-field range: this corresponds to both the peak with a higher field as shown in Fig. 4, and to the peak of $\lambda[1\bar{1}0]$ in Fig. 1(b). It is known that the ratio (d_{33}/χ) , in units of λ_{111}/M_s , has values about 2.1, 1.4, and 0.7 when domains rotate from the $[\bar{1}11]$ to the $[\bar{1}\bar{1}1]$ or $[11\bar{1}]$, from the $[\bar{1}11]$ to the $[111]$ axis, and from the $[\bar{1}\bar{1}1]$ or $[11\bar{1}]$ to the $[111]$ axis, respectively.¹¹ It would appear, therefore, that the observed peak seems to result from the redistribution of domain magnetizations from the $[111]$ to the $[\bar{1}11]$ or the $[11\bar{1}]$ directions. The peak with the lower field value in Fig. 4 may be mainly due to the redistribution of domains from the $[111]$ to the $[11\bar{1}]$ axis.

The mechanisms responsible for the domain redistributions in different ways has not been observed clearly so far by experiment.

The field dependencies of the magnetization and magnetostriction of the Laves phase pseudobinary $\text{Tb}_x\text{Dy}_y\text{Ho}_z\text{Fe}_{1.95}$ ($x+y+z=1$) compounds were measured as a function of compressive stress T ($10\text{ MPa} < |T| < 70\text{ MPa}$) and applied magnetic field H ($0 < H < 135\text{ kA/m}$). Values of x , y , and z were chosen to obtain minimum magnetic anisotropy and easy magnetization axis rotation near room temperature. At a compressive stress of 34 MPa , the addition of Ho to the binary $\text{Tb}_{1-x}\text{Dy}_x\text{Fe}_{1.95}$ compound reduced the width of the strain versus magnetic field hysteresis curves in $\text{Tb}_{0.28}\text{Dy}_{0.57}\text{Ho}_{0.15}\text{Fe}_{1.95}$ and $\text{Tb}_{0.26}\text{Dy}_{0.54}\text{Ho}_{0.2}\text{Fe}_{1.95}$ by 23% and 54%, respectively, compared to the original alloy, while the strains were reduced by only 7% and 10%. © 1998 American Institute of Physics. I. INTRODUCTION

The pseudobinary Laves phase $(R_x^1R_y^2\ldots)\text{Fe}_2$ compounds (R^i =rare earth, $x+y+\ldots=1$) are known to possess very large magnetostrictions, strong stress dependencies, and unusual ΔE effects.¹ The effects of crystalline anisotropy can be quite large in these materials, resulting in large hysteresis losses. Spin reorientation diagrams of the $\text{Tb}_{1-x}\text{Dy}_x\text{Fe}_2$ and $\text{Tb}_{1-x}\text{Ho}_x\text{Fe}_2$ ternary compounds show that the anisotropy can be minimized by a suitable combination of rare earths.² This kind of ternary alloy has one degree of freedom, x , which permits only the combined effects of all of the anisotropy constants to be minimized. In practice, this results in minimizing the largest anisotropy constant, K_1 .

By adding a third rare earth element, an additional degree of freedom is obtained and both of the two largest anisotropy constants, K_1 and K_2 can be minimized. Holmium is a good choice since, like Tb and Dy, it has a large, positive magnetostriction. This approach was followed by Williams and Koon³ who reported a very low anisotropy with the composition $\text{Tb}_{0.2}\text{Dy}_{0.22}\text{Ho}_{0.58}\text{Fe}_{1.95}$, but at the cost of substantially lowering the saturation magnetostriction. The reason for this lower magnetostriction is that Ho has only 1/3 of the intrinsic magnetostriction of Tb and Dy. In this article, we examine the reduction in the hysteresis losses and magnetostriction caused by substituting small amounts of Ho ($z \leq 0.2$) for Tb and Dy in the highly magnetostrictive $\text{Tb}_x\text{Dy}_{1-x}\text{Fe}_2$ pseudobinary.

II. EXPERIMENT

Five $\text{Tb}_x\text{Dy}_y\text{Ho}_z\text{Fe}_{1.95}$ ($x+y+z=1$) samples (0.48 cm diam \times 1.91 cm long) were prepared using a free standing zone melt method.⁴ A slightly iron deficient alloy

($\text{Fe}_{1.95}$ instead of Fe_2) is used in order to create a small amount of rare earth eutectic which thereby increases the mechanical robustness of the samples. The compositions examined in this study are shown in Table I along with the saturation magnetostriction S_{sat} . For a given Ho concentration, all of the samples except sample C lie on a linear minimum anisotropy line created by compounds of the form:

$$x(\text{Tb}_{0.15}\text{Ho}_{0.85}\text{Fe}_2) + (1-x)(\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2), \quad 0 \leq x \leq 1.$$

Sample A is the room temperature Terfenol-D composition and was used to provide a control for the experiment, while sample E is at the zero anisotropy composition found by Williams and Koon.³ Figure 1 shows these compositions on a ternary phase diagram. These relatively small diameter samples appear to be of very good quality since sample A (Terfenol-D) has a large magnetostriction and markedly lower hysteresis losses than larger size rods of the same composition. We believe this is due to good alignment of the $[112]$ platelets in these samples.

The magnetization and magnetostriction at compressive stresses T ($10\text{ MPa} < |T| < 70\text{ MPa}$) and fields H ($0 \leq H \leq 135\text{ kA/m}$) were measured at room temperature. The apparatus used a dead weight to apply the stress; length changes were measured by LVDTs, and the magnetization was measured by a small pickup coil wound around the

FIG. 1. Ternary phase diagram for the TbFe_2 - HoFe_2 - DyFe_2 system. The regions marked [100], [111], and [110] indicate the direction of the easy magnetization axis. The locations of the samples discussed in the article are indicated. The line of minimum anisotropy runs through samples A and E.

sample. Figure 2 shows the magnetostriction of a typical sample with Ho added (sample B). The primary objective of this work is to determine how the width of the hysteresis loop depends upon the Holmium concentration and compare this dependence with the decrease in magnetostriction as the Ho concentration was increased. For purposes of this comparison, we used application oriented measures of magnetostriction and hysteresis. The peak-to-peak magnetostriction S_{pp} is defined as the change in strain over a range of 71.6 kA/m (~ 900 Oe) centered around the field at which the piezomagnetic constant d has a maximum, subject to the restriction that the field is always positive, i.e., the center field is ≥ 35.8 kA/m. The hysteresis width W_h is defined as the average width of the magnetic field-strain curve at the field where d has a maximum.

Figure 3 shows S_{pp} as a function of Ho concentration and stress for samples A, B, D, and E, the samples that lie along the minimum anisotropy line. (Sample C, which lies on the Tb rich side of the minimum anisotropy line, has a

FIG. 2. Magnetostriction vs applied magnetic field for sample B, $\text{Tb}_{0.28}\text{Dy}_{0.57}\text{Ho}_{0.15}\text{Fe}_{1.95}$, for stresses of -9.8 , -21.9 , -33.9 , -46.0 , -58.1 , and -70.1 MPa.

FIG. 3. Peak-to-peak magnetostriction S_{pp} vs holmium concentration as a function of applied stress for samples A, B, D, and E.

slightly higher magnetostriction.) Figure 4 shows W_h as a function of Ho concentration and stress for the same four samples. For sample D ($\text{Tb}_{0.26}\text{Dy}_{0.54}\text{Ho}_{0.2}\text{Fe}_{1.95}$), at $T = -9.8$ MPa, an artifact of our definition of the width gave meaningless results: Part of the 71.6 kA/m magnetic field range used to determine W_h is at fields where the magnetostriction is saturated.

III. DISCUSSION

Figure 3 shows the reduction in S_{pp} as the Ho concentration is increased. The effect is moderately large at low stresses and decreases as the stress is increased and the applied stress begins to dominate the magnetostrictive behavior. At the same time, Fig. 4 shows that W_h also decreases as the Ho concentration increases. The reduction in S_{pp} and W_h for several of the stresses are summarized in Table II.

FIG. 4. Hysteresis width W_h vs Ho concentration for samples A, B, D, and E for applied stresses of -9.8 (filled square), -21.9 (filled triangle), -33.9 (filled diamond), -46.0 (filled circle), -58.1 (open square), and -70.1 MPa (open circle).

TABLE II. Fractional change in peak-to-peak magnetostriction $\Delta S = [S_{pp} - S_{pp}(A)]/S_{pp}(A)$ and fractional change in hysteresis width $\Delta W = [W_h - W_h(A)]/W_h(A)$ for samples B, C, D, and E as a function of applied stress. The reference values $S_{pp}(A)$ and $W_h(A)$ are the values for sample A.

$T(\text{MPa})$	Sample B		Sample C		Sample D		Sample E	
	ΔW	ΔS	ΔW	ΔS	ΔW	ΔS	ΔW	ΔS
-9.8	-49%	-9.4%	-3%	-16%	no data	-26%	-54%	-46%
-21.9	-20%	-8.5%	-10%	-12%	-10%	-16%	-48%	-39%
-33.9	-23%	-6.7%	-13%	-5.7%	-54%	-10%	-62%	-29%
-46.0	-26%	-5.9%	-15%	0.4%	-44%	-7.0%	-72%	-18%
-58.1	-18%	-4.2%	-33%	2.6%	-61%	-5.1%	-81%	-9.3%
-70.1	-36%	-7.2%	-21%	5.1%	-68%	-6.0%	-36%	-0.1%

In conclusion, small amounts of Ho (<20%) replacing Tb and Dy in the usual Terfenol-D formulation, while decreasing the magnetostriction, provide a much larger decrease in hysteresis losses. Such a tradeoff is very important for many device applications.

Terfenol-D, $\text{Tb}_{1-x}\text{Dy}_x\text{Fe}_2$ ($x \approx 0.7$), is successfully used as a magnetostrictive transducer material for low-frequency applications. To extend the frequency range of magnetostrictive transducers into the high kHz and MHz range, new materials processing techniques must be developed to minimize eddy current losses. The method that has demonstrated the greatest potential to date is based on rapid solidification by melt spinning to obtain thin strips of material. The objective of this program includes refining the casting procedure to yield ribbons with the [111] direction oriented along the length of the ribbon, with the (110) plane in the plane of the ribbon. The crystallographic orientation of the Terfenol-D ribbons have been controlled by varying the cooling rate of the melt-spinning process. The cooling rates were controlled by a number of parameters in the melt-spinning process and ribbons have been obtained with an enhancement of the (110) plane parallel to the surface of the ribbon. Magnetostrictive measurements under tensile stresses up to 3 MPa and magnetic fields up to 4 kOe yielded magnetostrictive displacements of 850×10^{-6} . © 1998 American Institute of Physics. [S0021-8979(98)25711-2]

INTRODUCTION

Terfenol-D, $\text{Tb}_{1-x}\text{Dy}_x\text{Fe}_2$ ($x \approx 0.7$), has one of the largest magnetostrictive displacements under ambient (room-temperature) operating conditions.¹ To date, the standard design for transducers that use Terfenol-D as the actuator incorporates a rod of the material cast under specific cooling conditions.² The cooling parameters are designed to generate a uniform crystallographic structure in the rod to obtain the largest possible magnetostrictive displacement. The large displacement increases the energy of the acoustic signal that is generated by the transducers.

One of the limits of this type of magnetostrictive transducer is the frequency range of the generated acoustic signal. The large size of the actuator rod limits the effectiveness of the transducer at higher frequencies due to eddy current losses.³ The optimal configuration for higher-frequency (ultrasonic) magnetostrictive transducers is to have thin layers of the material stacked to form the transducer rod. This maximizes the magnetostrictive behavior as it minimizes the eddy current losses that occur when the rod configuration is used, enabling generation of ultrasonic signals with frequencies in the low megahertz (MHz) range. This means that the alloy needs to be manufactured in thin strips with the appropriate crystallographic orientation. The method reported here for manufacturing thin strips of Terfenol-D is a modification of the melt-spinning rapid solidification technique.

The preferred direction of magnetization in Terfenol-D is [111] in the cubic Laves' phase.¹ For melt-spun ribbons, this means that this direction should be oriented along the length of the ribbon. To achieve this orientation, the (110) plane could lie in the plane of the ribbon, as the [111] direction is located in the (110) plane. The work that will be described here is an ongoing effort to develop methods to obtain this desired orientation in Terfenol-D ribbons by controlling the cooling rate of the melt-spinning process. The cooling rate is controlled by varying the velocity of the melt-spinning wheel and by changing the composition of the melt-spinning wheel, which yields different values for the thermal conductivity of the wheel.

EXPERIMENT

To generate ribbons of Terfenol-D, the melt-spinning technique commonly used for rapid solidification was used.⁴ A schematic of the melt spinner is shown in Fig. 1. The melt-spinning procedure was initiated by placing a 5 gm piece of nonoriented Terfenol-D in a quartz crucible, which, in turn, was placed inside an induction coil. The Terfenol-D was heated by induction heating just past the melt point, at which time it was ejected onto the spinning wheel through a 0.6 mm hole in the quartz crucible. The molten metal was ejected by applied argon gas. The melt-spinning process was performed inside an enclosed chamber under an argon atmosphere at ambient pressure to prevent oxidation. The velocity of the melt-spinning wheel was set by a controller and was

^{a)}Electronic mail: lindgren@indqual.com

FIG. 1. Schematic of the melt spinner used to manufacture Terfenol-D ribbons.

measured using an optical tachometer. Changes in the wheel velocity were used to control the cooling rate of the solidification process. Five wheel compositions that had values for the thermal conductivity that ranged from 2.0 to 0.29 W cm/K were investigated in combination with the wheel velocities to obtain a broad range of cooling conditions.

Using the melt-spinning technique, sections of ribbon over 100 mm in length were obtained. The dimensions of the ribbon depended on the wheel velocity, with thicknesses that ranged from 60 to 450 μm and widths from 1 to 5 mm. The crystallographic orientation of the ribbons was determined by x-ray diffraction (XRD). The ribbons were mounted on amorphous glass slides with tape. The mounting tape was placed outside the x-ray beam to insure that it did not affect the diffraction pattern. The samples were scanned at 2° per minute in a computer controlled Diano XRD 8535 x-ray diffractometer. Each diffraction pattern was analyzed by subtracting the background radiation and normalizing the diffraction pattern to itself. This was followed by normalizing the pattern to a powder diffraction pattern of Terfenol-D. The powder sample was obtained by crushing a section of the as-received Terfenol-D rod.

The magnetostrictive performance of the ribbon was determined using a custom measurement system. Figure 2 shows a schematic of the experimental apparatus. The ribbons were mounted between the pole faces of an electromagnet in a loosely fitting channel made of glass slides to keep the ribbon from swinging. Measurements on bulk Terfenol-D commonly utilize compressive stresses. Since it is not practical to apply a compressive stress to ribbons, a tensile stress was used instead. The upper end of the ribbon was clamped to an aluminum support rod with a rubber-jawed clamp. A similar clamp attached a weight holder to the lower end of the ribbon. Weights of 50, 100, 200, and 500 gm were hung from the weight holder to apply the stress. This resulted in average stresses of 0.31, 0.72, 1.4, and 2.7 MPa. Because the width and thickness of the ribbon varied with position, the local stress varied somewhat throughout the sample. Based on the variations of the ribbon's width and thickness, the estimated standard deviation of the stress is 15%. An MTI

FIG. 2. Schematic of experimental apparatus for measuring magnetostriction of melt-spun ribbons as a function of magnetic field and tensile stress.

1000 Photonic sensor was used to measure the motion of the bottom of the weight and a Lakeshore Gaussmeter was used to measure the applied field. It was found that the ribbon's magnetostriction stabilized after maintaining tension on the ribbon overnight.

Terfenol-D has a positive magnetostriction, which means that tensile stress aligns the moments along the length of the ribbon. In order to rotate the moments to measure the magnetostriction, a magnetic field perpendicular to the ribbon length must be applied, in this case, across the width of the ribbon. Because of the large length-to-width ratio of the sample and the orientation of the applied field with respect to the ribbon, the demagnetizing effect is significant. The demagnetizing field parallel to the width at the center of sample was calculated to be 700 Oe.⁵

FIG. 3. Normalized intensity of the (220) diffraction peak as a function of wheel velocity for the wheel with a thermal conductivity of 2.0 W cm/K.

FIG. 4. Normalized intensity of the (220) diffraction peak as a function of thermal conductivity of the melt-spinning wheel.

RESULTS AND DISCUSSION

The ability to control the crystallographic orientation of the Terfenol-D ribbon is shown in Fig. 3, which is a plot of the amplitude of the (220) diffraction peak as a function of wheel velocity for the wheel with a thermal conductivity of 2.0 W cm/K. While there is scatter in the trend of the amplitude of the (220) peak, especially at a wheel velocity of 8 m/s, the data show that slower wheel velocities, and therefore, lower cooling rates, yields ribbon with a greater amount of the (220) plane in the plane of the ribbon. Recall that this is the desired result as the [111] direction, the direction of maximum magnetostrictive displacement, is in the (220) plane.

The systematic dependence of the crystallographic orientation on the cooling rate of the melt-spinning process is further shown in Fig. 4, which shows the amplitude of the (220) peak as a function of the thermal conductivity of the melt-spinning wheel. The amplitude for the diffraction peaks was taken for the melt spinning performed with a wheel velocity of 2 m/s, except for the wheel with the lowest thermal conductivity. To obtain continuous ribbons with this wheel, the velocity was set to 13 m/s. Figure 4 clearly demonstrates that lower values of the thermal conductivity of the melt-spinning wheel will result in a greater amount of the preferred crystalline orientation in the Terfenol-D ribbons. Therefore, as illustrated by Figs. 3 and 4, it has been demonstrated that the velocity and composition of the melt-spinning wheel can be used to control the crystalline orientation of Terfenol-D.

Figure 5 shows the magnetostriction of the ribbon melt spun at 2 m/s on the wheel composition with a thermal conductivity of 0.4 W cm/K for two different tensile stresses.

FIG. 5. Magnetostriction vs applied field for Terfenol ribbon melt spun on the wheel with a thermal conductivity of 0.4 W cm/K at 2 m/s.

Each curve shows two magnetic-field sweeps overlaid. The data are repeatable (within 10% from day to day and when the stresses are removed and replaced). The detailed shape of the curve is quite similar to bulk Terfenol-D. This can be seen in the region around zero field where the double well shape is observed. The maximum magnetostriction was measured to be 850×10^{-6} , about half that of high-quality bulk material.

SUMMARY AND CONCLUSIONS

The results that have been obtained demonstrate the ability to manufacture continuous ribbons of Terfenol-D by melt spinning. The cooling rate of the solidification process was controlled by varying the velocity and the composition of the melt-spinning wheel. X-ray diffraction of the ribbons determined that the greater amount of the desired crystalline orientation, with the (110) plane in the plane of the ribbon, was obtained for the slowest cooling rates of the melt-spinning process. Magnetostrictive measurements indicate that the ribbons are not fully in the optimal crystalline orientation. The maximum value for the magnetostriction is approximately 50% that of the high-quality bulk materials.

Amorphous ribbons of an alloy with the composition $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{0.98}\text{B}_{0.02}$, which exhibit good magnetostrictive properties at low magnetic fields, are bonded with a phenol-based binder to fabricate bulk composites. Efforts to determine optimum fabrication parameters are made by examining magnetic and mechanical properties of bulk compacts obtained at various fabrication conditions. From the binder content dependence of magnetostriction and compressive strength, the optimum binder content is estimated to be about 4.3 wt %, taking into account magnetostrictive and mechanical properties and the necessity of reducing nonmagnetic binder content. The two properties of magnetostriction and compressive strength vary nearly linearly with the compaction pressure; as the compaction pressure varies from 0.25 to 1.0 GPa, magnetostriction decreases but compressive strength increases, making it difficult to determine the optimum compaction pressure. A magnetostriction of 493 ppm (at 1.1 kOe) is achieved from the present bulk composites, together with a high $d\lambda/dH$ (sensitivity of magnetostriction with applied magnetic field) of 1 ppm/Oe.

Cubic Laves RFe_2 (R: rare-earth elements) compounds possess giant magnetostriction at room temperature.¹ However, since the magnetocrystalline anisotropy of the compounds is also very large, intrinsically large magnetostriction is usually not realized at a magnetic field applicable in device applications. Two methods have mainly been used: alloy design and microstructural modification. In line with the latter method, it has been demonstrated for Dy-Fe,² Tb-Fe,³ and Tb-Dy-Fe alloys⁴ that very good magnetostrictive properties are achieved at low magnetic fields by grain refinement or amorphization. Since grain refinement or amorphization can most conveniently be done by melt spinning, the samples with good low-field properties are ribbon type and usually very brittle, which limit applications in the as-spun ribbon form. In an effort to solve this problem, rod-shaped composites are fabricated by combining amorphous melt-spun ribbons with a polymer binder. Amorphous ribbons of a $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{0.98}\text{B}_{0.02}$ alloy, which were melt spun at a wheel velocity of 50 m/s, were used in the composite fabrication, since from the previous study³ they were observed to exhibit good magnetostrictive properties at low magnetic fields. It is expected that with the inclusion of a polymer binder the frequency limit of the materials can be extended to high region due to high resistivity of composites. Furthermore, this way of producing R-Fe-based magnetostrictive bulk materials is simple and cost effective over the currently popular directional solidification process.

An alloy of $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{0.98}\text{B}_{0.02}$ was induction melted

and then melt spun in an Ar atmosphere at a wheel velocity of 50 m/s. The resultant ribbons were crushed to powders with a size below 45 μm . The powders were then mixed with a phenol-type binder, the amount of which was varied from 3.1 to 6.7 wt %. The mixed powders were compacted at varying pressures ranging from 0.25 to 1 GPa. Composites with high mechanical strength were finally obtained by curing at 150 °C. The dimension of the present composites is 3.5 mm×3.5 mm×10 mm (length). The microstructure of melt-spun ribbons was examined by x-ray diffraction and also by transmission electron microscopy. The magnetostriction (λ) of the ribbons was measured by a three-terminal capacitance method at magnetic fields (H) up to 8 kOe, while that of bulk composites by using a linear variable differential transformer type apparatus with a maximum magnetic field of 1.1 kOe. In the case of bulk materials, compressive stress was applied to the specimen during the measurement. Magnetic properties of both melt-spun ribbons and composites were measured with a vibrating sample magnetometer at magnetic fields up to 15 kOe. A mechanical tester was used to measure the compressive strength of cured composites. All the measurements were done at room temperature.

The microstructure of the as-spun ribbons mainly consists of an amorphous phase with a trace of the crystalline TbFe_2 phase. The magnitude of H_c of these ribbons is relatively low, being about 0.5 kOe, and, as expected, magnetostrictive characteristics are observed to be good, particularly at low magnetic fields. In Fig. 1 are shown the results for $\lambda-H$ plots for the as-spun ribbons. The value of λ shown in

^{a)}Electronic mail: mmlshl@kistmail.kist.re.kr

FIG. 1. λ - H plots for the amorphous ribbons of an alloy $(\text{Tb}_{0.33}\text{Fe}_{0.67})_{0.98}\text{B}_{0.02}$ in the as-spun state.

Fig. 1 is obtained by the relation $\lambda = \frac{2}{3}(\lambda_{\parallel} - \lambda_{\perp})$. Here, λ_{\parallel} and λ_{\perp} are, respectively, the values of magnetostriction measured in the parallel and the transverse directions in the ribbon plane. The difference $(\lambda_{\parallel} - \lambda_{\perp})$ corresponds to the peak-to-peak value when rotating in-plane magnetic fields are applied. The value of λ is therefore the *intrinsic* magnetostriction at a given field, being independent of the domain structure. The reliability of the present magnetostrictive results for the as-spun ribbons is found to be good, as can be judged from the small scatter in the measured data. The small magnitude of saturation magnetostriction, together with good low-field magnetostrictive properties, is characteristic of a material with an amorphous structure.

One of the most important tasks during the fabrication of bulk composites is to conserve, as much as possible, the good magnetic and magnetostrictive properties of the melt-spun ribbons. As the process proceeds, however, these properties steadily deteriorate; for example, the (average) value of H_c of final bulk composites is increased to 1.0 kOe from the initial (average) value of 0.5 kOe of the melt-spun ribbons, the largest increase of H_c being observed during the milling process. It is worth noting here that saturation magnetization (actually, magnetization at 15 kOe, M_{15}) remains nearly unchanged during the whole process; rather, a slight increase is observed from 53.4 to 56.5 emu/g during the compaction process to form green compacts. No deterioration of M_{15} indicates that all fabrication processes are well controlled. This is of particular importance, since some of the processes such as pressing were performed in air. This is made possible by the fact that each powder is completely coated by the binder, thus preventing powder/air contact. During the early stage of work when the fabrication conditions were not optimized, a very large reduction of M_{15} occurred during the fabrication processes involving air atmosphere, due to the incomplete coverage of powders with polymer binder.

Magnetostriction of bulk composites was measured only in the parallel (length) direction, since, with the present sample dimension, demagnetizing fields are very large in the transverse direction and, furthermore, an accurate estimation of them is not easy in this direction. It is noted that, from the

FIG. 2. The magnitude of λ_{\parallel} as a function of applied compressive stress during the measurement. The results are for the bulk composites fabricated at the compaction pressure of 0.5 GPa and the binder content of 6.7 wt %.

applications point of view, the magnitude of λ_{\parallel} is much more important than that of λ_{\perp} , since the applied magnetic field is usually in the length direction. Unlike λ , the magnitudes of λ_{\parallel} and λ_{\perp} depend on the domain structure, and therefore, they are expected to vary with applied (compressive) stress, the spin direction being affected via magnetoelastic interactions. The results for λ_{\parallel} are shown in Fig. 2 as a function of applied compressive stress during the magnetostriction measurement. The results are for the sample fabricated at a compaction pressure of 0.5 GPa and a binder content of 6.7 wt %. The value of λ_{\parallel} increases with increasing compressive stress. This is expected since more spins can be directed towards the transverse direction by the application of larger compressive stress. Saturation in the plot of λ_{\parallel} versus applied compressive stress is reached at about 16 MPa, indicating that at this stress spins are aligned nearly completely in the transverse direction. In later measurements, the applied compressive stress is fixed at 16 MPa.

Magnetic (including magnetostrictive) and mechanical properties of bulk composites with varying binder contents from 3.1 to 6.7 wt % were investigated and some results for λ_{\parallel} and compressive strength are shown in Figs. 3(a) and 3(b), respectively, for the samples fabricated at a fixed compaction pressure of 0.5 GPa. It is seen from the figures that the magnitude of λ_{\parallel} is increased substantially as the binder content is varied from 3.1 to 4.3 wt %, but is little affected by further increase of the binder content. The small magnetostriction at the low binder content may result from the fact that the strain produced in a particle does not transfer efficiently to neighboring particles due to the lack of binder. On the other hand, compressive strength increases continuously with increasing binder content. Although large mechanical strength is desirable in some applications, it is also important to reduce the amount of nonmagnetic binder content in order to have a material with a high performance/volume ratio. With this consideration, the optimum binder content is considered to be around 4.3 wt %, large magnetostriction being combined with relatively large compressive strength. However, in some applications where large compressive strength is required, composites with a high binder content may preferably be used.

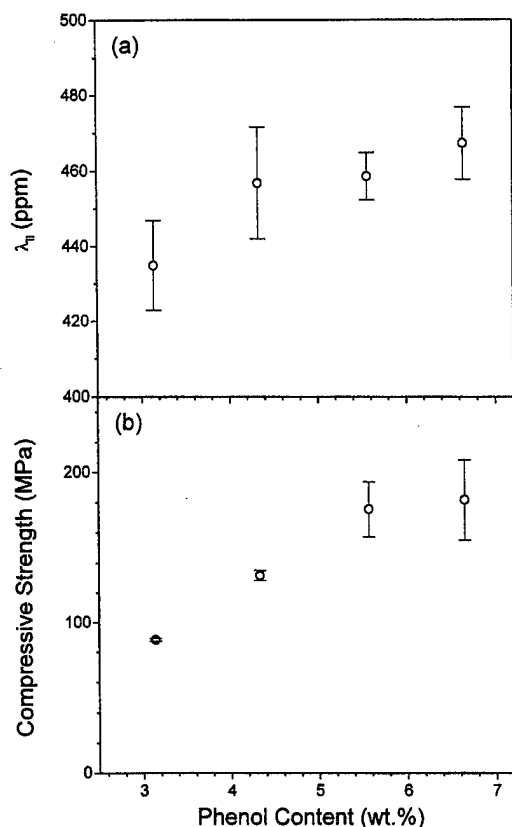

FIG. 3. The magnitude of (a) λ_{\parallel} (measured at a compressive stress of 16 MPa) and (b) compressive strength as functions of the binder content. The composites are fabricated at a fixed compaction pressure of 0.5 GPa.

In Figs. 4(a) and 4(b) are shown the results for λ_{\parallel} and compressive strength as functions of the compaction pressure. The compaction pressure is varied from 0.25 to 1.0 GPa and the results shown in Figs. 4(a) and 4(b) are for the compacts with a fixed binder content of 4.3 wt %. From these figures it is observed that, as the compaction pressure increases, the magnetic property of λ_{\parallel} deteriorates, while the mechanical property of compressive strength improves. Since the compaction pressure dependence of the two properties varies nearly linearly, it is hard to decide the optimum compaction pressure. Rather, the compaction pressure can be determined depending on particular applications; for example, in applications where large magnetostriction is required but mechanical strength is not of prime importance, bulk samples fabricated at low compaction pressure may be used.

The highest (average) magnitude of λ_{\parallel} obtained in this work is just below 500 ppm (493 ppm), which is equivalent to the value of 329 ppm for λ , with the assumption of complete spin alignment in the transverse direction via magnetoelastic interactions by the applied compressive stress during the measurement. The value of λ estimated from the bulk composites is higher than the value of 310 ppm obtained for the melt-spun ribbons. The increase of the "intrinsic" λ value for the bulk composites, though very small, is not clearly understood. One possibility is that a small portion of an amorphous phase is transformed into the crystalline phase

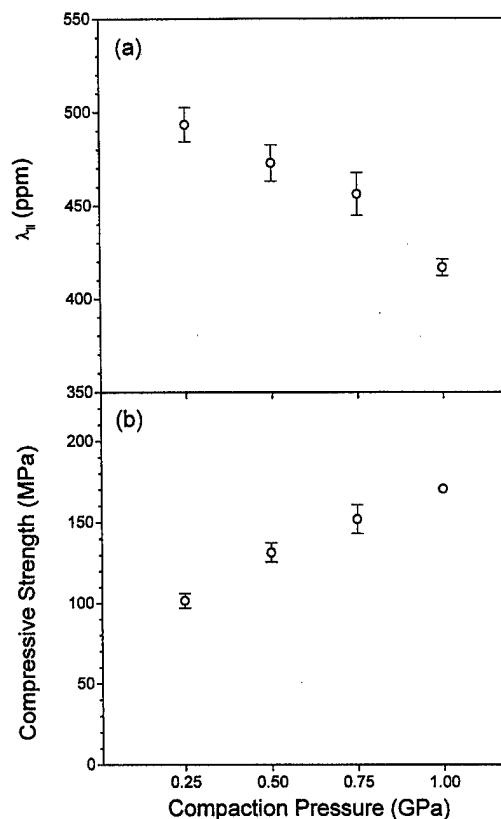

FIG. 4. The magnitude of (a) λ_{\parallel} (measured at a compressive stress of 16 MPa) and (b) compressive strength as functions of the compaction pressure. The composites are fabricated at a fixed binder content of 4.3 wt %.

in the course of the bulk fabrication. This may also explain a slight increase of M_{15} of bulk composites, compared with the initial melt-spun ribbons.

Equally good magnetostrictive properties are also obtained at intermediate magnetic fields. For example, at a magnetic field of 0.64 kOe (which is the smallest magnetic field applied to measure the melt-spun ribbons), the magnitude of λ_{\parallel} for bulk composites is 384 ppm (which is equivalent to the intrinsic value of 256 ppm). This value is nearly equal to the value of 260 ppm for the melt-spun ribbons. However, at magnetic fields below 0.2 kOe, the magnetostriction of the bulk composites is very small. This can be actually expected by the increase of H_c during the fabrication processes, since low-field magnetostrictive properties are sensitive to H_c .⁵ The problem of small low-field magnetostriction may be solved by the application of a bias magnetic field. In applications, the sensitivity of magnetostriction with magnetic field ($d\lambda/dH$) as well as the absolute magnitude of magnetostriction is considered to be an important property. In this work, a high sensitivity of over 1 ppm/Oe is also achieved in the present bulk composites.

Young's modulus, magnetization, and magnetostriction measurements were made as a function of applied magnetic field ($0 < H < 160$ kA/m) and compressive stress ($8.5 \text{ MPa} < |T| < 57.3 \text{ MPa}$) in [100] single crystal DyZn at 77 K. Piezomagnetic d constants greater than 300 nm/A and changes in Young's modulus greater than 40 GPa were found. Pronounced features are abrupt changes in the elastic moduli, magnetostriction, and coupling factors arising from "jumps" in the magnetization occurring as the moment changes from one easy [100] axis to another. The characteristic magnetic fields at which this change occurs depend strongly upon the stress induced magnetic anisotropy. Magnetomechanical coupling factors reach 0.91. © 1998 American Institute of Physics. [S0021-8979(98)34511-9]

I. INTRODUCTION

Morin *et al.*¹ have shown that large values of magnetostriction exist in rare-earth-zinc compounds having the CsCl structure. These values are only slightly smaller than those found in the heavy rare earth elements themselves. Recently, measurements of the piezomagnetic properties were reported for single crystal $\text{Tb}_{1-x}\text{Dy}_x\text{Zn}$ for $x=0, 0.4$, and 0.5 .²⁻⁴ From these observations and more extensive magnetization and magnetomechanical measurements on polycrystals, a magnetic easy axis phase diagram for $\text{Tb}_{1-x}\text{Dy}_x\text{Zn}$ ($0 \leq x \leq 0.5$) was obtained.^{3,5} In this article, we report measurements of piezomagnetic properties of DyZn at 77 K that occur during the magnetization process and compare these measurements with those for TbZn, $\text{Tb}_{0.6}\text{Dy}_{0.4}\text{Zn}$, and $\text{Tb}_{0.5}\text{Dy}_{0.5}\text{Zn}$. In all the measured rare-earth-zinc compounds to date, the $\langle 100 \rangle$ axes are the easy magnetization axes at 77 K and huge magnetostrictive distortions occur as the magnetization changes from one easy direction to another. In the following sections, piezomagnetic d constants, permeabilities, and Young's moduli under constant magnetic field, Y^H , and magnetic induction, Y^B , are reported. From these measurements, magnetomechanical coupling factors were calculated.

II. EXPERIMENT

Single crystals of DyZn were prepared at the Materials Preparation Center, Ames Laboratory, Ames, IA by a Bridgman growth technique using sealed Ta crucibles.⁶ For this study a large cylindrical single crystal sample ($1.92 \text{ cm} \times 0.65 \text{ cm}$ diam) with its axis oriented along the easy [100] direction was selected. Compressive stresses $8.5 \text{ MPa} < |T| < 57.3 \text{ MPa}$ and magnetic fields $0 < H < 160$ kA/m were applied along the long dimension of the cylinder. Magnetostriction as a function of H was obtained by (1) conventional strain gage methods and (2) LVDT's po-

sitioned to measure overall sample length changes. The magnetization was determined simultaneously by integrating the voltage of a pickup coil wound around the center of the sample. The results are shown in Fig. 1. Compressive stresses lower the energies of the [010] and [001] easy directions perpendicular to the rod axis. (Only a small compressive stress is needed to rotate all of the magnetic moments toward the perpendicular easy axes.) The presence of a relatively strong magnetocrystalline anisotropy can be seen in the magnetization versus field and the magnetostriction versus field curves. As a magnetic field is applied, three distinct magnetic regions are observed: (1) a low field region con-

FIG. 1. Magnetization and magnetostriction vs magnetic field of single crystal DyZn along the easy [100] axis at 77 K for stresses from -8.5 to -57.3 MPa.

^{a)}Electronic mail: restorff@oasys.dt.navy.mil

sisting of a stress controlled magnetic moment rotation away from the perpendicular easy axes, (2) a region of high permeability and magnetostriction where the magnetic moments jump discontinuously from a direction near the perpendicular easy axes to the easy [100] axis along the rod, and (3) magnetic saturation. The region of high permeability and magnetization “jumping” broadens as the compressive stress is increased. We attribute this broadening to stress inhomogeneities within the sample giving rise to 90° domains which are mobile at fields below those required for magnetization rotation.

Young's moduli under constant magnetic field, Y^H , and under constant magnetic induction, Y^B , were measured as a function of magnetic field at fixed stresses, T , of -24.8 and -44 MPa. These moduli were obtained by changing the stress by ± 3.25 MPa and measuring the average strain registered by two strain gages attached on opposite sides of the sample for different values of the applied field.

III. THEORY

For a simple single domain magnetization rotation process in cubic compounds, which is applicable to DyZn in the low field magnetization region, the energy can be written as a sum of a Zeeman term, magnetocrystalline anisotropy terms, stress anisotropy terms, and an elastic term, as follows:

$$E_{\text{tot}} = -M_s \sum H_i \alpha_i + K_1 (\alpha_1^2 \alpha_2^2 + \alpha_2^2 \alpha_3^2 + \alpha_3^2 \alpha_1^2) \\ + K_2 \alpha_1^2 \alpha_2^2 \alpha_3^2 - (3/2) \lambda_{100} T (\sum (\alpha_i^2 \beta_i^2) - (1/3)) \\ - (3/2) \lambda_{111} T \sum_{i \neq j} \alpha_i \alpha_j \beta_i \beta_j + E_{\text{el}}.$$

Here M_s denotes the saturation magnetization in tesla; λ_{100} and λ_{111} are the cubic magnetostriction constants; K_1 and K_2 are the fourth order and sixth order cubic anisotropy constants, α_i and β_i are the direction cosines of the magnetization and stress direction, respectively; and E_{el} is the conventional elastic energy expression for cubic crystals. (Since K_1 is strongly positive and the magnetization remains in the (001) plane, the λ_{111} term can be neglected.)

Figure 2 illustrates the magnetic behavior for $(3/2)\lambda_{100} = 4.8 \times 10^{-3}$ and $M_s = 2.0$ T, using values of $K_1 = 1, 3, 5$ ($\times 10^5$ J/m³). Three regions, similar to the three observed in DyZn, are predicted for all values of $K_2 > -2 \times 10^6$ J/m³. In the low magnetic field region, the susceptibility, dM/dH , is given by $M_s^2/(2K_1 - 3\lambda_{100}T)$, and the piezomagnetic d constant, $d\lambda_{100}/dH$, is given by $3\lambda_{100}TM_s^2H/(2K_1 - 3\lambda_{100}T)$. As K_1 is increased, the susceptibility decreases and the jumping region moves to lower fields. For $K_1 \rightarrow \infty$, $H_{\text{sat}} \rightarrow -(3/2)\lambda_{100}T/M_s$. From these expressions values of K_1 can be obtained. In the magnetization jumping region, the susceptibility is given by $1/N$ and the piezomagnetic constant is given by $(3/2)\lambda_{100}/NM_s$, where N is the demagnetization factor. For very large negative values of K_2 , the magnetization jumps out of the (100) plane toward a $\langle 111 \rangle$ direction and back into the (100) plane, yielding two discontinuities in the magnetization and magnetostriction curves as seen in Fig. 2(b). This is not observed in DyZn.

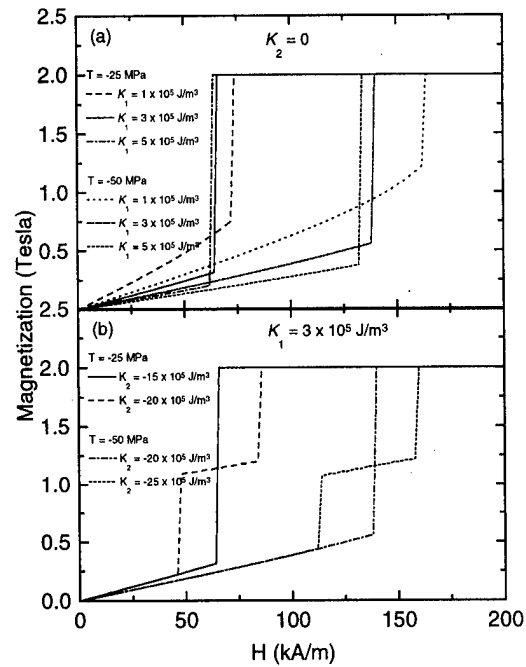

FIG. 2. Magnetization vs magnetic field for the single domain rotation model in cubic single crystals with field parallel to [100], $\lambda_{100} = 3.2 \times 10^{-3}$ and $M_s = 2.0$ T.

It is important to note that the total lowest order anisotropy constant, K_1^{TOT} , in magnetostrictive materials has two sources: (1) an intrinsic source, K_1 , and (2) a contribution which arises from the magnetostriction through the elastic energy term, ΔK_1 . When a cubic material is free to strain under magnetization rotation (constant external stress), the presence of magnetostriction gives rise to a contribution to the anisotropy not included in the K_1 term above. (For a clamped lattice, there is no magnetostrictive contribution to the anisotropy.) Substituting equilibrium strains into the elastic energy term above yields the total value of K_1 (at constant stress) to be:

$$K_1^{\text{TOT}} = K_1 + (9/4)[(c_{11} - c_{12})\lambda_{100}^2 - 2c_{44}\lambda_{111}^2].$$

IV. DISCUSSION

From the low field region of Fig. 1, the value of K_1^{TOT} for DyZn is found to be 2.9×10^5 J/m³. In Table I are compared the values of K_1^{TOT} calculated for DyZn, Tb_{0.5}Dy_{0.5}Zn, Tb_{0.5}Dy_{0.5}Zn, and TbZn. Also, in the table, calculated values of ΔK_1 , using elastic constants reported by Morin and Schmitt⁷ are listed for DyZn and TbZn. The calculated contributions to K_1^{TOT} from the magnetostriction are substantially larger than those observed in the DyZn and TbZn com-

TABLE I. Measured values of K_1^{TOT} and calculated values of $\Delta K_1 = (9/4)(c_{11} - c_{12})\lambda_{100}^2$ at 77 K.

	DyZn ($\times 10^5$ J/m ³)	Tb _{0.5} Dy _{0.5} Zn ($\times 10^5$ J/m ³)	Tb _{0.6} Dy _{0.4} Zn ($\times 10^5$ J/m ³)	TbZn ($\times 10^5$ J/m ³)
K_1^{TOT}	2.9	0.5	1.9	3.1
ΔK_1	8.3	10.0

pounds. Thus we conclude that the major source of K_1^{TOT} is not the intrinsic anisotropy, but the contribution arising from the change in anisotropy with strain, i.e., the magnetostriction.

For technical purposes, it is often important to know the modulus of the magnetostrictive material. In the region of magnetization jumping, where the material is most useful, the modulus is substantially lowered (ΔE Effect) due to easy domain wall motion. As a stress is applied in this region, the sample changes length by the softer magnetization process rather than by the much stiffer interatomic elasticity. Thus in a magnetically free sample, a dip is observed in the elastic modulus (Y^H) as a function of magnetic field. This dip is always reduced when the induction B is kept fixed as the stress is applied. In a material containing a single domain, the dip in Y^B disappears completely because the length change occurs only by the compression of atomic distances between the atoms. In a multidomain sample, 90° domain walls are often redistributed by the stress, resulting in a soft-

TABLE II. Relative permeability, μ_R , piezomagnetic d constant, d , Young's moduli, Y^H and Y^B , and magnetomechanical coupling factor, k , of DyZn at 77 K. $k = (1 - Y^H/Y^B)^{1/2}$.

T (MPa)	H (kA/m)	μ_R	d (nm/A)	Y^H (GPa)	Y^B (GPa)	k
-11.8	30	110	360
-24.8	31	54	295	5.0	30	0.91
-44.0	54	30	140	6.6	28	0.87

ening of the sample even though the total induction B is kept constant. The extent of the Y^B dip depends upon the ease of antiparallel 90° domains moving with respect to antiparallel 180° walls.

In Fig. 3 are plotted Young's moduli Y^H and Y^B for compressive stresses of -24.8 and -44 MPa. Note the large ΔE effect. A maximum of $Y^B/Y^H \approx 6$ is reached during the magnetization process. Since the magnetomechanical coupling $k = (1 - Y^H/Y^B)^{1/2}$, these results imply highly efficient transduction. Table II lists values of the piezomagnetic d constants, permeabilities, Young's moduli, and magnetomechanical coupling factors for stresses of -13.3 , -31.1 , and -44.0 MPa. The high coupling factors, high saturation magnetostriction, and high magnetization make the $\text{Tb}_{1-x}\text{Dy}_x\text{Zn}$ compounds attractive materials for low temperature actuators, valves, and transducers.

X-ray magnetic circular dichroism (XMCD) measurements have been performed under high pressure and used to study the disordered $\text{Fe}_{72}\text{Pt}_{28}$ Invar alloy in conjunction with x-ray diffraction. The high spin to low spin state transition is observed by both techniques and is compared with previous work. Furthermore, XMCD gives the first evidence of the complete disappearance of the magnetic moment at high pressure in this alloy. It also proves the existence of an hysteresis cycle due to the pressure-dependent magnetic moment. © 1998 American Institute of Physics. [S0021-8979(98)41011-9]

INTRODUCTION

Many transition metal alloys have been found to present magnetic volume instabilities. In certain composition range, binary and ternary alloy systems show Invar behavior.¹ In such systems, the thermal expansion is invariant in a large temperature range about the room temperature. Theoretical calculations² have shown the coexistence of two magnetic states energetically closed (about 1.5 mRy) in these systems: a high spin state (HS) centered at high volume with a large magnetic moment and a low spin state (LS) centered at low volume with a small magnetic moment. At low temperature, the HS state is totally occupied. With increasing temperature, population of the LS state is expected leading to an equal occupation of the two states at high temperature. Thus the Invar anomaly is explained with the compensation of the lattice expansion by the occupation of this low spin and low volume state. The $\text{Fe}_{72}\text{Pt}_{28}$ compound is known to be a strong ferromagnet showing an Invar anomaly. In the special case of the ordered Fe_3Pt ,³ calculations have predicted a pressure-induced transition from the HS to the LS state, i.e., a collapse of the magnetic moment. Mössbauer-effect spectroscopy experiments⁴ have given experimental evidence of this transition.

X-ray magnetic circular dichroism⁵ (XMCD) appears to be a meaningful technique in probing the magnetic properties of matter because of its double selectivity (element and orbital). In this paper, we will present the first high-pressure XMCD measurements which have been performed on the disordered $\text{Fe}_{72}\text{Pt}_{28}$ compound at the PtL_3 edge. High-pressure diffraction experiments have also been carried out and we will discuss the magnetic behavior of the compound in view to its structural properties.

HIGH-PRESSURE DIFFRACTION EXPERIMENTS

Figure 1 shows the evolution of the lattice constant with pressure for the disordered $\text{Fe}_{72}\text{Pt}_{28}$ alloy obtained by the high-pressure diffraction experiments. From the discontinuity of the lattice constant expansion rate corresponding to a change of the compressibility coefficient we have found that the transition from the mixture of HS and LS states to a pure LS one is complete at a critical pressure of about 4 GPa. Below 4 GPa, the lattice parameter decrease is due to the sample compression and the HS/LS transition. Above 4 GPa, the only contribution to the lattice parameter decrease is the sample compression in the LS state. The fact that no difference in the five fcc structure diffraction lines indexing were detected below and above the critical pressure shows that no structural phase transition occurs. In the whole pressure range, the fcc lattice remains stable.

FIG. 1. Lattice parameter as a function of pressure for the $\text{Fe}_{72}\text{Pt}_{28}$ disordered compound.

In the pressure ranges below and above 4 GPa, the lattice constant pressure dependence can be well fitted with the Murnaghan equation at the first order:

$$a = a_0(1 + B'_0 P/B_0)^{-1/3B'_0},$$

where B_0 and B'_0 are, respectively, the bulk modulus and its first derivative at $P=0$. We find the bulk modulus values of 78 ± 8 and 167 ± 7 GPa, respectively, below and above 4 GPa.

Ultrasonic waves experiments⁶ (USW) have been made on the $\text{Fe}_{72}\text{Pt}_{28}$ disordered crystal. They have found at room pressure and room temperature a value of 114 GPa for the bulk modulus which is very much larger than the one we have found (78 GPa). The difference between the two values could be explained by the fact that ultrasonics measurements at room pressure do not provoke the HS/LS transition. The only contribution to the bulk modulus is the sample compression in the mixture of the HS and LS state. Therefore the bulk modulus deduced from ultrasonics has to be compared with that measured in a state where no magnetovolumic effect takes place, i.e., in the pure LS state. From the B_0 and B'_0 parameters values above 4 GPa, we have extrapolated the bulk modulus of the LS state with a lattice parameter corresponding to the room pressure one. We have found a value of 167 GPa; the sample in the mixture of the HS and LS state is more compressible than in the LS state. Since the compressibility is directly related to the number of bonding electrons, in a crude approximation, more electrons are involved in the LS state binding than in the HS one. Podgorny⁷ has calculated the electronic contribution in the bonding of Fe–Pt alloys. In strong ferromagnets such as $\text{Fe}_{72}\text{Pt}_{28}$ in the HS state, the majority Fe 3d band is full and has no bonding properties. He has shown that the electrons implied in the binding of Fe–Pt alloys are mainly from the Fe 3d minority band hybridized with the Pt 5d minority band. Under compression, the number of Fe minority electron increases leading to a magnetic moment decrease. This may support our view concerning the number of electrons implied in the bonding since the LS phase corresponds to the magnetic state at high pressure.

HIGH-PRESSURE XMCD EXPERIMENTS

The high-pressure XMCD experiments have been carried out on the energy dispersive x-ray absorption beamline D11 at DCI, Orsay. The polychromator was a bent silicon (111) crystal, focusing right at the sample position located between the poles of an electromagnet (0.3 T), where the high-pressure cell is placed. Right circularly polarized photons were selected by a slit set 0.3 mrad below the orbit plane of the storage ring and the magnetic field was reversed to make the XMCD measurements.

Figure 2(a) presents the XMCD spectra at 2.5 GPa of the disordered $\text{Fe}_{72}\text{Pt}_{28}$ at the PtL_{III} edge and the signal obtained is directly related to the magnetic moment of the Pt 5d band. Our results at room pressure are in good agreement with former works which have been made on this compound.⁸ The existence of the XMCD spectra shows a spin polarization of the Pt 5d band induced by the Fe 3d band. This

FIG. 2. (a) Normalized XMCD signal at the PtL_{III} edge of the disordered $\text{Fe}_{72}\text{Pt}_{28}$ compound at 2.5 GPa. (b) Evolution of the XMCD integral at increasing (full circle) and decreasing (empty circle) pressure.

polarization results from two factors: the Fe spin polarization, which depends on the Fe–Fe distance, and the Fe–Pt hybridization. The sign of the spectra indicates a ferromagnetic coupling between the Pt and the Fe moments.

Figure 2(b) shows the integral of the spectra of the disordered $\text{Fe}_{72}\text{Pt}_{28}$ at different pressures. For the disordered alloy, an increase of the pressure from 2 to 4 GPa decreases the XMCD signal and indicates a magnetic phase transition. From 4 GPa, the signal is stabilized with a lower intensity, and we attribute this first magnetic phase transition to the well-known transition from the mixture of the HS and the LS state to the pure LS state.

Around 13 GPa, the XMCD signal decreases drastically and vanishes totally above a critical pressure of 20 GPa. This is the first experimental evidence of a pressure-induced magnetic moment collapse in this compound. The disordered $\text{Fe}_{72}\text{Pt}_{28}$ undergoes a magnetic transition from the LS state to a nonmagnetic state (NM) as expected from theoretical calculations.³

The first transition from the HS to the LS state has already been observed at 4.2 K at about the same pressure by Abd-Elmeguid *et al.* using ^{57}Fe high-pressure Mössbauer spectroscopy (MS).⁴ In addition, MS follows the pressure dependence of the Curie temperature. At about 8.2 GPa, the T_c of the disordered phase is 40 K which is in contradiction with the existence of a XMCD signal above this pressure at room temperature. MS experiments have also been performed on the ordered phase of the $\text{Fe}_{72}\text{Pt}_{28}$ compound and the transition from the HS to the LS state has been observed at a critical pressure of 6 GPa. A pressure dependence of the Curie temperature has been observed and the value of T_c at 7.1 GPa is about 110 K.

We have also measured the pressure-dependent XMCD signal of the ordered phase of $\text{Fe}_{72}\text{Pt}_{28}$ at 300 K. The XMCD signal decreases before 6 GPa and at about 9 GPa the signal is already very small. The XMCD magnitude decreases because of the concomitant pressure dependence of the Curie temperature and the HS–LS transition. In the special case of the ordered phase, the transition from the HS to the LS state followed by XMCD seems to be hidden by the thermal decrease of the magnetization.

FIG. 3. Magnetization as a function of temperature for the ordered and disordered $\text{Fe}_{72}\text{Pt}_{28}$ compound.

The temperature dependence of magnetization has been investigated for the two phases (Fig. 3). Compared to the ordered phase, the decrease of magnetization of the disordered phase is very soft around the Curie temperature. In the disordered phase, the Pt and Fe atoms are randomly distributed over all the sites of the fcc structure which leads to local fluctuations of concentration. Spatial inhomogeneities can lead to variations of Curie temperature which broadens the distribution of the magnetization curve. Under compression, the difference of the Curie temperature between various domains may be enhanced leading to a broadening of the paramagnetic transition width: at high pressure the magnetization should still remain well above the Curie temperature.

In the disordered compound, the flat part of the XMCD curve in the pressure range above 4 GPa proves that the system is in the LS state. According to MS results, the Curie temperature is around room temperature in the pressure range of the HS/LS transition and the thermal decrease of the magnetization is an additional cause of the decreasing XMCD signal. In parallel, we have to consider the increase of Pt spin polarization due to the strengthening of hybridization with pressure which leads to the opposite trends, i.e., an

increase of the XMCD signal. At the Pt L edges, XMCD probes the 5d band of platinum and according to other studies⁹ the orbital moment of the 5d band is less than 10% of the total magnetic moment. Consequently, the XMCD signal is directly related to the spin polarization of the 5d. Because of the volumic compression, the overlap between the Fe 3d band and the Pt 5d band increases leading to a larger spin polarization of the platinum induced by the hybridization with the spin polarized 3d band of iron. This reinforcement of hybridization counterbalances part of the decrease of the spin polarization of platinum. This effect may fully counterbalance the decrease of the XMCD signal expected from thermal effects.

When the pressure is released, the XMCD signal of the disordered phase appears at about 5 GPa and finally the integral of the XMCD signal at room pressure is stabilized at a value which is lower than the initial HS state one. At the same time, diffraction experiments have shown that the volume of the sample after releasing the pressure is the same as the one obtained in the HS initial state. We have clearly shown that the $\text{Fe}_{72}\text{Pt}_{28}$ alloy undergoes directly the transition from the NM to the HS states when the pressure is released. The existence of such a cycle of hysteresis in the evolution of the magnetic moment is in good agreement with the calculations of Podgorny.³ This proves that such compounds can have different magnetic states with the same crystallographic structures, depending on the history of the system.

To obtain FeB amorphous plated films with soft magnetization and high magnetostriction, effects of three kinds of agents [sodium L-ascorbate ($C_6H_7NaO_6$), thiourea (NH_2CSNH_2), and ammonium sulfate ($(NH_4)_2SO_4$)] on magnetic and magnetoelastic properties of films were investigated systematically. The first two agents, $C_6H_7NaO_6$ and NH_2CSNH_2 were found to be ineffective for improving the soft magnetic properties of films. To the contrary, however, $(NH_4)_2SO_4$ is very effective for the magnetic softening: Amorphous FeB plated films with coercivity less than 4 Oe were obtained by employing the bath composition of $FeSO_4 \cdot 7H_2O$ (71.9 mM), KBH_4 (296.6 mM), NaOH (400 mM), $KNaC_4H_4O_6 \cdot 4H_2O$ (600 mM) and $(NH_4)_2SO_4$ (80 mM). These soft films exhibited a favorable large magnetostriction of 26×10^{-6} , being adequate for micromagnetoelastic devices. © 1998 American Institute of Physics. [S0021-8979(98)41111-3]

I. INTRODUCTION

Recently, we have demonstrated that amorphous FeB films are obtained by electroless plating.¹ The resultant film thickness was, however, very thin due to low catalytic activity of iron. To overcome this problem, we employed electroplating technique and showed that thick amorphous FeB films can be formed by carefully controlling the bath temperature and current density.² The plated films unfavorably exhibited hard magnetic properties (20–50 Oe coercivity) and small magnetostriction, although the alloy film prepared by physical means such as sputtering generally has very soft magnetization and large magnetostriction simultaneously. Thus, magnetic softening of the plated films has become indispensable for using the films in practical micromagnetoelastic devices.³

Certain agents for reducing the coercivity of plated alloy films exist with the choice depending on the alloy systems and the plating mechanism. For instance, Kim *et al.*⁴ showed that sodium L-ascorbate ($C_6H_7NaO_6$), acting as an oxidation prevention agent for ferrous ion, was effective for the magnetic softening of NiFe electroless plated films. For CoNiFe plated films, however, thiourea (NH_2CSNH_2) is useful, because NH_2CSNH_2 causes the reduction in CoNiFe grain sizes, yielding the reduction in coercivity of the alloy films.⁵ Appropriate choice of complexing agent can also lead to the magnetic softening, as is the case for the CoB electroless plated films of Osaka *et al.*,⁶ made with a combined complexing agent of sodium tartrate ($Na_2C_4H_4O_6 \cdot 2H_2O$) and ammonium sulfate ($(NH_4)_2SO_4$).

In this study, therefore, the effects of the above three kinds of agents ($C_6H_7NaO_6$, NH_2CSNH_2 , and $(NH_4)_2SO_4$) on magnetic and magnetoelastic properties of amorphous FeB plated films have been investigated, so as to obtain electrochemically an alloy film with soft magnetization and large magnetostriction which are comparable to those of sputtered films.

II. PLATING OF AMORPHOUS FeB FILMS

Let us briefly describe the plating conditions for obtaining amorphous FeB film, because the effects of all additional agents were studied based on the original conditions. Table I shows the composition of original plating bath; iron sulfate ($FeSO_4 \cdot 7H_2O$) and potassium borohydride (KBH_4) were used as the sources for iron and boron. Sodium hydroxide (NaOH) was used as a pH control agent, while potassium sodium tartrate ($KNaC_4H_4O_6 \cdot 4H_2O$) was used as a complexing agent. The plating bath was prepared, by first dissolving the $KNaC_4H_4O_6 \cdot 4H_2O$ in distilled water, whose temperature was about 25 °C. Then, the $FeSO_4 \cdot 7H_2O$ was added and dissolved. After dissolving $FeSO_4 \cdot 7H_2O$ completely, the NaOH solution and KBH_4 were added. The preparation procedure

TABLE I. The basic plating bath compositions.

Iron sulfate	$FeSO_4 \cdot 7H_2O$	71.9 mM
Potassium borohydride	KBH_4	296.6 mM
Sodium hydroxide	NaOH	400 mM
Potassium sodium tartrate	$KNaC_4H_4O_6 \cdot 4H_2O$	318.9 mM

FIG. 1. Coercivity vs $C_6H_7NaO_6$ concentration in bath.FIG. 2. Coercivity vs NH_2CSNH_2 concentration in bath.

of plating bath as well as the amount and the temperature of distilled water in which $KNaC_4H_4O_6 \cdot 4H_2O$ was dissolved are very important for preventing the precipitation of iron hydroxide. The bath temperature during the film deposition was kept below $35^\circ C$, because the alloy film with amorphous structure could not be obtained when the film was formed at above that temperature. With the current density of $1 A/dm^2$, amorphous $Fe_{80}B_{20}$ film with about $1 \mu m$ thickness was formed after 30 min. deposition.

III. EXPERIMENT

The effects of additional agents were studied by dissolving the individual agents into the bath solution (Table I). The bath with $C_6H_7NaO_6$ was obtained by dissolving $C_6H_7NaO_6$ (5.04–10.1 mM) prior to dissolving $KNaC_4H_4O_6 \cdot 4H_2O$. In this case, the concentration of $KNaC_4H_4O_6 \cdot 4H_2O$ was 600 mM. The bath with NH_2CSNH_2 was prepared by dissolving NH_2CSNH_2 (0.263–1.31 mM) into the base solution after all other ingredients were mixed without changing the original composition. As for the bath with $(NH_4)_2SO_4$, $(NH_4)_2SO_4$ (0–100 mM) was added into the base solution after dissolving $KNaC_4H_4O_6 \cdot 4H_2O$. In this case, however, the concentration of $KNaC_4H_4O_6 \cdot 4H_2O$ was changed, ranging from 200 to 600 mM. The reason is that $(NH_4)_2SO_4$ and $KNaC_4H_4O_6 \cdot 4H_2O$ form a combined complex agent, and the complexing effect of the combined agent is presumably governed by this ratio.

In all cases, bath temperature was maintained at $30 \pm 2^\circ C$ during the film formation by using automatic thermostat mechanism equipped for the bath. The film substrates were copper foils and glass plates covered with Cu ($100 \mu m$ thick)/Cr ($50 \mu m$ thick) double layers. The Cr underlayers, which were directly deposited on the glass plates, were used to prevent the exfoliation of the top Cu layers during plating.

IV. RESULT AND DISCUSSION

Figure 1 shows the change in coercivity of films versus the concentration of $C_6H_7NaO_6$. Although $C_6H_7NaO_6$ was expected to be effective for magnetic softening by decreasing the dissolved oxygen and preventing oxidation of ferrous ion in the bath, no apparent change in the coercivity of amorphous FeB plated film was observed. This indicates that the

hard magnetic properties of films are not caused by the dissolved oxygen in the bath. The amount of dissolved oxygen in the bath is unclear, but is considered to be negligible. This is because KBH_4 as the boron supplier also acts as a reducing agent whose reducing power is presumably sufficient for reducing the dissolved oxygen without $C_6H_7NaO_6$.

Figure 2 shows the change in coercivity of films versus the concentration of NH_2CHNH_2 , where the current intensity i is taken as a parameter. The coercivity of films unfavorably increased by the addition of NH_2CHNH_2 to about 100 Oe, suggesting the existence of crystal phase in films. In fact, x-ray diffraction peaks corresponding to α -Fe phase were observed for these films. This situation is well explained from Fig. 3, showing that the boron content of these films is markedly reduced by the addition of NH_2CHNH_2 , which results in the change in crystallographic structure of films from amorphous to polycrystalline. Then, in our plating system, NH_2CHNH_2 is less attractive agent for magnetic softening of amorphous FeB films.

Contrary to the above two cases, addition of $(NH_4)_2SO_4$ was found to be very effective for reducing the coercivity of plated films. Figure 4 shows a coercivity map, in which coercivities of the films are plotted as a function of the concentrations of both $(NH_4)_2SO_4$ and $KNaC_4H_4O_6 \cdot 4H_2O$. The film coercivities vary depending strongly on the concentrations of $KNaC_4H_4O_6 \cdot 4H_2O$ and $(NH_4)_2SO_4$, but in general they be-

FIG. 3. Boron content vs NH_2CSNH_2 concentration in bath.

FIG. 4. Coercivity of the film vs $\text{KNaC}_4\text{H}_4\text{O}_6$ and $(\text{NH}_4)_2\text{SO}_4$ concentration in bath.

come smaller when the concentrations of these agents are increased simultaneously. Especially, for the combination of $\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$ (600 mM) and $(\text{NH}_4)_2\text{SO}_4$ (80 mM), the film exhibited a coercivity less than 4 Oe, suggesting that the use of combined complex agents composed of $\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$ and $(\text{NH}_4)_2\text{SO}_4$ is very effective for magnetic softening. Because of the wide variety of coercivities of films, the magnetic softening was considered due to the change in film compositions. Then, film compositions for all samples in Fig. 4 were evaluated. The results are summarized in Fig. 5 as a composition map with respect to the concentrations of complex agents. In comparison with Fig. 4, meaningful correlation between the coercivity and the composition of films is not seen: the composition of film with coercivity of 4 Oe is 30 at. % from Fig. 5, but the coercivity

FIG. 5. Boron content of the film vs $\text{KNaC}_4\text{H}_4\text{O}_6$ and $(\text{NH}_4)_2\text{SO}_4$ concentration in bath.

of films with the same composition varies from sample to sample in Fig. 4. Therefore, the change in film composition is not responsible for the magnetic softening.

Apart from the mechanism of magnetic softening with the combined complex agent, the plated FeB films exhibiting such a small coercivity are very attractive for micromagnetoelastic devices. In this case, films are required to exhibit large magnetostriction as well as the soft magnetic properties. The plated film with soft magnetic properties showed a considerably large magnetostriction of 26×10^{-6} . Since the magnetostriction of plated films which have been formed without using $(\text{NH}_4)_2\text{SO}_4$ is as small as 1×10^{-6} , the use of a combined complex agent is thus also useful for improving the magnetoelastic properties of films through magnetic softening.

V. CONCLUSION

It is concluded that the use of combined complex agent composed of $\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$ and $(\text{NH}_4)_2\text{SO}_4$ is useful for obtaining amorphous FeB plated films with small coercivity and large magnetostriction. The use of $\text{C}_6\text{H}_7\text{NaO}_6$ or NH_2CSNH_2 is, however, less effective for magnetic softening of the FeB plated films contrary to other alloy systems such as NiFe^4 and CoNiFe films.⁵

The mechanism of magnetic softening by the combined complex agent is still unclear, although the changes in grain sizes and/or crystallographic structures of films are likely to be responsible. To clarify this, further investigations are now under progress, together with the determination of optimum plating conditions for obtaining amorphous FeB films with soft magnetization and large magnetostriction.

Field-induced strain under load in Ni–Mn–Ga magnetic shape memory materials

S. J. Murray, M. Farinelli, C. Kantner, J. K. Huang, S. M. Allen, and R. C. O'Handley
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Single-crystal Ni_2MnGa shows a nearly 0.2% strain under a magnetic field of 8 kOe at -8°C . Polycrystalline samples have been prepared near stoichiometry to study the composition dependence of the magnetic and elastic properties. A narrow band of compositions has been found having a range of Curie and martensitic transformation temperatures, T_C and T_0 , extending to above room temperature. The compressive stress-strain characteristics in variable transverse field were studied in samples selected to have T_0 just below room temperature. Stress-induced martensite was observed as expected and the magnetic field was applied under fixed load for various stresses. A transverse field of 3200 Oe caused the sample to strain under load doing work that increased up to 1.3 J/kg with increasing volume fraction of stress-induced martensite. © 1998 American Institute of Physics. [S0021-8979(98)41211-8]

I. INTRODUCTION

Very large magnetic-field-induced free strains (no load) have been observed in the low-temperature phase of certain magnetic alloys that show a martensitic transformation and exhibit the associated shape-memory effect.¹ A field-induced, free strain of 0.2% was reported^{2,3} in single crystals of Ni_2MnGa at -8°C . James and Wuttig⁴ reported a free strain 0.5% in single crystals of FePd at -17°C . Further, James and Wuttig have observed⁵ that a stress-cooled, off-stoichiometry, single crystal of Ni_2MnGa shows a field-induced, free strain of 1.3% below 0°C . Clearly, these magnetic martensitic materials already surpass piezoelectric materials and magnetostrictive materials such as Terfenol-D, in their ability to generate free strain. They can be expected to have potential in a variety of actuation devices and smart materials.

There is new science to be uncovered as we understand better how the twin boundaries in these shape memory materials respond to the application of a magnetic field as well as to stress. Progress is already being made in this direction.^{4,6,7} The observations of this magnetic shape memory effect reported so far indicate some of the major challenges faced in advancing these materials toward application:

- (1) The operating temperature of these materials must be increased.
- (2) Their performance under significant loads must be characterized.
- (3) These characteristics should be sought in more robust, and (probably) polycrystalline materials.

This paper describes results that begin to address each of these issues. Polycrystalline samples of Ni–Mn–Ga alloys have been made that show martensitic transformation temperatures in excess of 40°C and that are ferromagnetic to higher temperatures. So far these samples show only relatively small magnetic-field-induced strains, possibly because

they are untextured. Further, the strain under loads up to 110 MPa has been measured in NiMnGa polycrystals at room temperature.

II. EXPERIMENT

Several samples weighing approximately 50 g each were induction melted and some were vacuum cast. Pieces were cut from these samples for magnetometry, field-induced strain and mechanical testing. Magnetometry was done in fields up to 10 kOe at temperatures from 200 to 400 K. Field-induced strain was measured using metal foil strain gauges and a bridge circuit. The field range accessible here was ± 5 kOe over temperatures of 200 to 400 K. Field-induced strain under load was measured using an Instron machine fitted with a hybrid electro-permanent magnet capable of fields up to 3.2 kOe.

III. RESULTS

A. Composition dependence

The polycrystalline samples were characterized by three fundamental parameters that are believed to be critical to observing magnetic-field-induced strains in shape memory alloys. These are saturation magnetization, M_s , Curie temperature, T_C , and martensitic temperature, T_{mart} . M_s is important because the magnetic pressure driving twin boundary motion is given by $2M_sH$. Further, the material should be in the martensitic state at the operating temperature, $T < T_{\text{mart}}$, and operation at or above room temperature is an immediate goal. The variation of M_s , T_C , and T_{mart} are given in Table I for some of the polycrystalline samples made.

These results are shown graphically in a ternary phase diagram, Fig. 1, which defines the field of $M_s > 45$ emu/g, $T_C > 70$ and 80°C , as well as $T_{\text{mart}} > 20$ and 40°C . Samples having appreciable magnetization and T_{mart} in the ferromagnetic phase at or above room temperature are found in a band of compositions stretching roughly from $\text{Ni}_{50}\text{Mn}_{29}\text{Ga}_{21}$ toward $\text{Ni}_{44}\text{Mn}_{34}\text{Ga}_{22}$. While these samples are of importance for further development, in this paper we focus on the inter-

TABLE I. Saturation magnetization, M_s , Curie temperature, T_C , and martensitic transformation temperature, T_{mart} , of some polycrystalline Ni-Mn-Ga alloys.

Composition			M_s (emu/gm)	T_C (Centigrade)	T_{mart} (Centigrade)

esting behavior of $\text{Ni}_{50}\text{Mn}_{28}\text{Ga}_{22}$ alloy which is austenitic at room temperature and martensitic below 12 °C.

B. Temperature dependence

The field induced strain of single crystal Ni_2MnGa has been reported above and below the transformation temperature.^{2,3} It is of interest to know the details of the temperature dependence of the strain associated with twin boundary motion. The top part of Fig. 2 shows the temperature dependence of the magnetization measured in $H = 100$ Oe. The magnetization step at T_{mart} is a reflection of the stronger magnetic anisotropy in the tetragonal martensitic phase. The saturation magnetization is fairly continuous through the transformation. The lower part of Fig. 2 shows the variation of the strain, e_0 , with increasing and decreasing temperature about T_{mart} . e_0 is measured in a saturating field parallel to the strain gauge and is negative.

Note that the strain in the martensitic phase ($T < 12$ °C) is more than an order of magnitude smaller than

FIG. 2. Above, temperature dependence of magnetization in $H = 100$ Oe on cycling polycrystalline $\text{Ni}_{50}\text{Mn}_{28}\text{Ga}_{22}$ through its martensitic transformation temperature. Below, temperature variation of field-induced strain in a saturating field. Inserts show the field dependence of the strain above and below T_{mart} as well as the definition of e_0 .

that reported in single crystals of the stoichiometric compound.^{2,3} The reasons for this are not yet clear but it may be due to the polycrystalline nature of the material or to the presence in this sample of impurities that impede twin boundary motion. The strain increases on cooling from the austenitic phase, making an abrupt increase with the appearance of twinning below 12 °C. On heating from the low-temperature phase there is a clear peak in field-induced strain just below the transformation temperature. This may be a manifestation of lattice softening near the transformation. This peak is less pronounced on cooling than on heating from deep in the martensitic phase because in the latter case the material is more fully transformed and more twinning would have occurred than on first cooling through T_{mart} .

C. Strain under load

Polycrystalline $\text{Ni}_{50}\text{Mn}_{28}\text{Ga}_{22}$ is interesting from another point of view that exploits its austenitic state at room temperature. Figure 3 shows that this material exhibits what is commonly referred to as stress-induced martensite when the

FIG. 1. Partial ternary phase diagram for polycrystalline Ni-Mn-Ga alloys showing M_s , T_C , and T_{mart} fields of interest. The solid dots show the stoichiometric composition, Ni_2MnGa and the location of $\text{Ni}_{50}\text{Mn}_{28}\text{Ga}_{22}$ which is focused on in this paper.

FIG. 3. Stress-strain curve taken on polycrystalline $\text{Ni}_{50}\text{Mn}_{28}\text{Ga}_{22}$ at room temperature (austenitic) using an Instron machine. The nonlinearity is evidence of stress-induced martensite. The insert, lower right, shows the field induced strain under constant load from the starting point indicated by the solid dot on the σ - e curve.

austenitic phase is loaded at temperatures not too far above T_{mart} . On first loading the material, it shows a stiffness characteristic of the high-temperature phase. However, at higher loads, some regions transform to martensite and twins form with a preferred orientation that effectively accommodates the applied load. On reducing the load, the stress-induced martensite reverts to austenite and the large strain is returned, hence the name superelasticity.

It is interesting for several reasons to use this stress-induced martensite as a starting material for measuring field-induced strain. First, the twins formed are preferentially aligned by the applied load. Second, observation of significant field-induced strain above the transformation temperature would extend the temperature range over which these materials would be useful. Third, such measurements provide strain-under-load data that are not yet available on these magnetic shape memory materials.

The insert in Fig. 3 shows the strain achieved in an applied field of 3.2 kOe transverse to the load axis, at a constant load of 108 MPa, (600 lbs over a 0.25 cm^2 area). The solid dot on the stress strain curve locates the starting condition. The solid line extending to the left of the dot indicates the nature of the experiment, i.e., the applied field causes the material to reverse the strain induced by the load which is held constant. The strains measured here in 3.2 kOe are considerably larger than those shown in Fig. 2 in the austenitic phase (taken in 6 kOe); they are comparable in magnitude to those measured in the martensitic phase. The sign of the field-induced strain is consistent with a free-energy model for martensite-austenite phase boundary motion⁷ and with the observed destabilization of the martensitic phase in a magnetic field.²

The work done by the sample on the Instron machine during field actuations is 11 kJ/m^3 (or 1.3 J/kg). This is comparable to the work output of Terfenol-D actuators (10 to 20 kJ/m^3) reported by Clark *et al.*⁸ Perhaps more importantly, if one connects the greatest free strain yet measured on single crystal NiMnGa⁵, namely 1.3% , with the load bearing ability of the polycrystalline samples, in excess of 110 MPa , the potential for mechanical work output can be inferred to be of order 715 kJ/m^3 (90 J/kg). This estimate of the potential of magnetic shape memory materials to do work compares very favorably with the comparable quality factor for Terfenol-D, namely $0.24\% \times 100 \text{ MPa}/2 \approx 120 \text{ kJ/m}^3$.

Magnetoelastic behavior of the Heusler Ni_2MnGa alloy

Eduard Obradó,^{a)} Alfons González-Comas, Lluís Mañosa, and Antoni Planes

Departament d'Estructura i Constituents de la Matèria, Facultat de Física, Universitat de Barcelona, Av. Diagonal 647, E-08028 Barcelona, Spain

In this work the effect of the interplay between magnetic and structural degrees of freedom in the structural transitions undergone by Ni_2MnGa alloy is investigated. Elastic constant and magnetic susceptibility measurements in a magnetic field are presented. A simple phenomenological model is proposed to account for the experimental observations. © 1998 American Institute of Physics. [S0021-8979(98)25911-1]

I. INTRODUCTION

The Ni_2MnGa alloy is the only known ferromagnetic material exhibiting a martensitic transition from a high temperature Heusler structure towards a close-packed phase.^{1,2} Associated with this phase transition, this material exhibits shape memory properties.³ These properties are related to the ability of the system to reverse large deformations in the martensitic phase by heating the alloy up to the high temperature phase. The interest of ferromagnetic compounds compared with other shape memory alloys is the possibility of magnetic field control of the shape memory properties. The potentiality of the Ni_2MnGa alloy for such a purpose has been recently proved by Ullakko and co-workers.⁴ They have shown that the application of a magnetic field provokes a tendency of the martensitic variants to be aligned with the field. As a consequence, the field modifies the induced transformation strain.

More fundamental is the fact that, in this material, the martensitic transition is preceded by the appearance of a micromodulated structure which is accompanied by the condensation of a $q=0.33\text{ TA}_2$ phonon.⁵ Recently, we have shown^{6,7} that this premartensitic structure develops via a weakly first order transition. Since such a premartensitic transition is not observed in other nonferromagnetic materials, it seems reasonable to believe that it is a consequence of a magnetoelastic interaction.

In this paper we show the existence of magnetoelastic effects in this material, from elastic constant and magnetic susceptibility measurements in an applied magnetic field. The relevance that the magnetoelastic interplay between structural and magnetic degrees of freedom has on the premartensitic transition is finally discussed in the framework of a Landau model.

II. EXPERIMENTAL RESULTS

A single crystal grown by the Bridgman method with composition very close to stoichiometric Ni_2MnGa was investigated. From the original rod two samples were cut using a low-speed diamond saw. The smaller sample ($3.1 \times 1.0 \times 1.4\text{ mm}^3$) was used in ac susceptibility measurements. The

larger one ($6.75 \times 4.8 \times 11.45\text{ mm}^3$), which had its faces parallel to the (110), ($\bar{1}\bar{1}0$), and (001) planes, was used in ultrasonic measurements.

Magnetic susceptibility measurements were conducted on an ac susceptometer. The elastic constants were obtained from ultrasonic measurements (pulsed-echo technique). In these ultrasonic measurements, a magnetic field up to 1 T was applied.

The Ni_2MnGa sample investigated displays a bcc structure with an $L2_1$ atomic order (space group $Fm\bar{3}m$) at high temperature. It orders ferromagnetically below $T_c=381\text{ K}$, and it transforms martensitically to a modulated tetragonal structure at $T_M=175\text{ K}$. The premartensitic transition occurs at $T_I=230\text{ K}$.

Clear evidence of the existence of a magnetoelastic interaction is the dependence of the elastic properties on the magnetic structure of the solid. To show this for Ni_2MnGa , we have measured its elastic constants under different magnetic fields, at room temperature. Prior to each measurement, the sample was subjected to a thermal treatment to ensure that the measured dependence of each elastic constant corresponded to the first magnetization process. A typical example of the behavior found is presented in Fig. 1, which shows the evolution of the three independent elastic constants as functions of a magnetic field applied along the

FIG. 1. Relative changes of the elastic constants (solid symbols) as functions of a magnetic field applied along the [100] direction. Open symbols correspond to the square of the magnetization extracted from Ref. 4. The inset shows the relative changes of the elastic constants as functions of the square of the magnetization.

^{a)}Electronic mail: eol@clyde.ecm.ub.es

FIG. 2. Real (χ' , squares) and imaginary (χ'' , circles) parts of the magnetic susceptibility as functions of temperature measured for $H_{dc}=10$ Oe and $f=66$ Hz. The inset shows the dependence of the temperature of the intermediate transition with a magnetic field applied along the [100] direction.

[100] direction. As the magnetic field is increased, all the elastic constants slightly increase up to a saturation value. Similar behavior is obtained with the magnetic field applied along the $[\bar{1}10]$ direction: the same saturation values are obtained (within experimental error) but at a larger value of the magnetic field. In order to prove that the measured change in the elastic constants is due to a change in the value of the magnetization, and is not due to rotation of the equilibrium magnetization, we have plotted the square of the magnetization (M) measured by Ullakko and co-workers in a similar sample.⁴ A good correlation exists between the change in the elastic constants and that of M . In the inset we have plotted the relative change of the elastic constants as functions of M^2 . It is interesting to note that, within the experimental errors, the same linear behavior is observed for low and high values of M^2 . At intermediate values, the data points deviate from this linear behavior. Such a deviation can be ascribed to the fact that ultrasonic and magnetic measurements have been conducted on different specimens and also to minor misalignments of the magnetic field in both sets of measurements which can result in slightly different values for the saturation field.

The interplay between the magnetic and structural degrees of freedom is also apparent in the change of the magnetic properties of the alloy as it goes through the structural phase transitions. This behavior is illustrated in Fig. 2, which shows an example of the evolution of the real (χ') and imaginary (χ'') parts of the magnetic susceptibility as functions of temperature. χ' has a significant change at around 175 K associated with the martensitic transition, and it displays a small anomaly at around 230 K. Such an anomaly is located at the temperature where a peak in the specific heat curve has been measured,⁶ and it is related to the condensation of the $q=0.33$ TA_2 phonon. At the temperatures of the structural transitions, χ'' increases; this is an indication of a

dissipative effect which, in each case, is due to the motion of domain boundaries.⁶ This phenomenon is in agreement with a measured increase in the internal friction at these phase transitions.⁸ Another manifestation of the magnetoelastic interplay is a dependence of the temperature of the premartensitic transition upon the magnetic field. In particular, for a first order phase transition the Clausius–Clapeyron law must hold. We have explored such a possibility by applying a low dc magnetic field along the [100] direction during the measurement of the ac susceptibility. We have found that T_I decreases with increasing magnetic field as shown in the inset of Fig. 2. These low magnetic fields do not modify the martensitic transition temperature and do not affect the characteristics of this transition. Fields in the range of several kOe are needed to induce significant changes in the characteristics of the martensitic transition.

III. DISCUSSION AND CONCLUSIONS

The results presented above give clear evidence for the existence of magnetoelastic coupling in Ni_2MnGa . In this section we would like to discuss the relevance of this coupling to the features of the premartensitic and martensitic transitions undergone by the studied alloy. We first introduce a Landau model suitable to describe the phase transitions of this system. The primary order parameter is taken to be the amplitude of the $q=0.33$ TA_2 phonon (related to the micro-modulation at the premartensitic transition), and we consider two secondary order parameters: ϵ , a (110)[$\bar{1}10$] homogeneous shear adequate to describe a cubic to tetragonal change of symmetry, and the magnetization M (considered to be a scalar). We assume the following general form of the Landau free energy:

$$\mathcal{F}(\eta, \epsilon, M) = F_{str}(\eta, \epsilon) + F_{mag}(M) + F_{me}(\eta, \epsilon, M), \quad (1)$$

where F_{str} is a purely structural term, F_{mag} is the magnetic term, and F_{me} is the contribution accounting for the magnetoelastic coupling. The explicit free energy expansion takes into consideration the symmetries of the system and the fact that the two structural transitions take place well below the Curie point, resulting in a breaking of the $\pm M$ invariance in the free energy. For the premartensitic transition, minimization of \mathcal{F} with respect to ϵ and M [which yields a path $\epsilon=0$, $M=M(\eta)$], leads to the following effective free energy:⁷

$$\mathcal{F}_{eff} = \frac{1}{2} A \eta^2 + \frac{1}{4} B \eta^4 + \frac{1}{6} C \eta^6, \quad (2)$$

where A is a linear function of temperature and of the high temperature phase magnetization M_0 ; B and C are temperature-independent functions of M_0 . It is interesting to point out that for large enough magnetoelastic coupling, B can be negative, and in this case the system can show a first order transition before becoming dynamically unstable ($A \rightarrow 0$). Within this picture, the softening of the characteristic phonon is expected to be incomplete at the transition, in accord with experimental observations.⁵ From this model the dependence of T_I on an externally applied magnetic field can be obtained. It is given by (Clausius–Clapeyron equation):

$(dT_I/dH) = -\alpha M_0/(1 + \alpha|\Delta S|)$, where α is a parameter related to the magnetoelastic coupling and ΔS is the entropy change at the premartensitic transition. From calorimetric measurements $\Delta S = -0.04$ J/K mol has been determined in the absence of magnetic field. The decrease of T_I with H (inset in Fig. 2) appears to be in agreement with the above equation.⁹ Even more, the above expression provides a justification for the nonlinear dependence shown in the figure: as the phase transition moves towards lower values, the stability limit of the high temperature phase is approached and the absolute values of ΔS are expected to decrease.

In nonferromagnetic alloys, the martensitic transition has been related to an anharmonic coupling between the TA_2 phonon and the homogeneous strain ϵ .¹⁰ In our model, this term is supposed to be negligible in comparison with the magnetoelastic coupling term. Nevertheless, it is worth noting that the magnetoelastic interaction indirectly couples η and ϵ . At the martensitic transition, ϵ becomes different from zero and a close-packed tetragonal phase is obtained. Such a symmetry change is accompanied by a change in the wave vector of the transverse modulation. In order to account for such a change in the Landau model, an explicit wavevector dependence of the Landau free energy should be considered.

Up to now, the microscopic origin of the magnetoelastic coupling in Ni_2MnGa has not yet been established. Short wavelength anomalies preceding the martensitic transition have also been observed in Ni-Al alloys.¹¹ They have been related to specific nesting properties of the multiply connected Fermi surfaces.¹² Nevertheless, Ni-Al is not ferromagnetic and no premartensitic transition has been observed in this alloy. In addition, in Ni-Mn-Ga alloys close to stoichiometric Ni_2MnGa but with less Mn content, the premartensitic transition is not observed although a magnetoelastic coupling has been proven to exist.¹³ We suggest that this different behavior could be due to the fact that the substitution of Mn by Ni atoms causes an increase in the martensitic transition temperature,¹⁴ and the magnetoelastic coupling is likely to be weaker. These two features imply that the bcc phase transforms to a close-packed one (martensitic transition) at a temperature higher than the temperature at

which the intermediate transition would occur (which is essentially controlled by the magnetoelastic coupling), and therefore, the micromodulated phase cannot develop independently of the martensitic transition in alloys with low Mn content.

To conclude, we have experimentally proven the existence of a magnetoelastic coupling in Ni_2MnGa . By means of a simple Landau-type model, it has also been shown that such a coupling leads to a first order phase transition that occurs as a lock-in of a soft phonon in the TA_2 branch. A knowledge of the microscopic origin of such a coupling and its relationship to the martensitic transition is still lacking.

Trial on-silicon micromagnetoelastic devices

M. Takezawa, M. Yamaguchi, K. Ishiyama, and K. I. Arai

Research Institute of Electrical Communication, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-8577, Japan

This paper discusses two new kinds of micromagnetoelastic devices made on silicon wafer whose function is to control the permeability of magnetostrictive soft magnetic thin films by voltage-controlled elastic strain. One is piezoelectric type and the other is electrostatic type. Structure, fabrication process, characteristics, and maximum possible output are discussed. The feasibility of these devices has been clarified although the rate of obtained permeability change was less than 1%. These device characteristics could be improved to 11% for piezoelectric type and to 80% for electrostatic type by the optimization of device dimensions and reduction of process damage to the magnetic film. © 1998 American Institute of Physics. [S0021-8979(98)41311-2]

I. INTRODUCTION

Magnetostrictive thin-film materials are of current interest for microfabricated sensors,¹ actuators,^{2,3} magnetosurface acoustic wave (MSAW) devices,⁴ etc. A potential benefit of these devices is the capability of silicon integrated intelligent systems. However, little work has been reported on the combination of magnetostrictive films and silicon.³

Therefore, this paper discusses two new kinds of micromagnetoelastic devices made on a silicon wafer whose function is to control the permeability of magnetostrictive soft magnetic thin film by voltage-controlled elastic strain. One is piezoelectric type and the other is electrostatic type.

The piezoelectric type is the extension of our previous work¹ that used FeSiB film and bulk PZT. In this work we microfabricated a FeSiB/ZnO double layer film structure on a silicon membrane. The electrostatic type utilizes bending of FeSiB film-substrate beam caused by electrostatic force. The space to bend is formed by anisotropic etching of silicon. Feasibility of these devices is demonstrated in this paper.

II. FILM MATERIALS

A. Magnetostrictive FeSiB film

The 0.5 μm thick $\text{Fe}_{77}\text{Si}_{11}\text{B}_{12}$ amorphous film was rf-sputter deposited onto a surface oxidized (100) orientated silicon wafers. The Ar gas pressure was 3.3 Pa and the rf power was 100 W ($5.7 \times 10^2 \text{ W/m}^2$). The as-deposited film had saturation magnetostriction of 33×10^{-6} , Curie temperature of 703 K, and a crystallization temperature of 743 K. These are similar to the published values.⁵

The stress release annealing without magnetic field was applied up to 673 K at below 2.7×10^{-4} Pa, which resulted in a remarkable coercive force decrease from 1990 A/m to 32 A/m and a permeability increase from 90 to 2300, as shown in Fig. 1. Then the films were annealed again in a static magnetic field of 39.8 kA/m at below 8.0×10^{-4} Pa for 2 h in order to stabilize the uniaxial anisotropy. The anisotropy field was increased from 200 to 280 A/m, and the squareness ratio, M_r/M_s along easy axis of magnetization was improved from 0.9 to nearly unity.

B. ZnO piezoelectric film

A 1 μm thick ZnO film was rf-sputter deposited on a surface oxidized (100) orientated silicon wafer using Ar: $\text{O}_2 = 8:2$ mixture gas. The total gas pressure was 4.0 Pa. The rf power was 100 W ($5.7 \times 10^2 \text{ W/m}^2$) and the substrate temperature was 473 K. The x-ray diffraction pattern of the film showed that the c axis was perpendicular to the film plane and its dispersion was 4 degrees. Since the threshold c -axis dispersion to degrade the piezoelectric properties is 6 degrees,⁶ crystal orientation of the fabricated ZnO film is adequate for the proposed sensors. The resistivity was $4 \times 10^9 \Omega\text{cm}$, which is similar to the published values.^{7,8}

The piezoelectric constant d_{31} was measured using a $\text{Au}(0.4 \mu\text{m})/\text{ZnO}(3 \mu\text{m})/\text{Cr}(0.5 \mu\text{m})$ multilayer film rf-sputtered on (100) orientated silicon wafer. The Cr and Au films were used as electrodes. The measured strain was almost proportional to the applied dc voltage of $\pm 2 \text{ V}$ as shown in Fig. 2. The readout of d_{31} was $-5 \times 10^{-12} \text{ m/V}$, which is similar to the published values.⁶

C. FeSiB/ZnO double layer film

Figure 3 shows the annealing temperature dependence of initial permeability of FeSiB film deposited on the 1 μm thick ZnO film substrate. The as-deposited FeSiB film on ZnO film had permeability higher than single layer FeSiB

FIG. 1. Annealing temperature dependence of coercive force and permeability.

FIG. 2. Applied voltage dependence of ZnO strain.

film because of tensile stress given by the ZnO under layer. With raising the annealing temperature, the permeability reached 1000 at 673 K and was further enhanced to 1500 by static magnetic field annealing of 39.8 kA/m at below 8.0×10^{-4} Pa for 2 h. The value obtained is slightly degraded compared to the single layer FeSiB film but still compatible to that.

III. PIEZOELECTRIC TYPE DEVICE

Figure 4 shows the schematic view of the magnetostrictive-piezoelectric type microdevice. A $0.5 \mu\text{m}$ thick SiO_2 under layer, $0.5 \mu\text{m}$ thick FeSiB film, $0.5 \mu\text{m}$ thick Cr electrode layer, $6.5 \mu\text{m}$ thick ZnO piezoelectric film, $3 \mu\text{m}$ thick SiO_2 over layer and $2 \mu\text{m}$ thick Cr electrode layer were rf-sputter deposited in turn onto the (100) oriented silicon wafer. The main parts are FeSiB/ZnO double layers of $12 \text{ mm} \times 13 \text{ mm}$ rectangle area. Then the wafer was anisotropically etched from the back side in tetramethyl ammonium hydroxide (TMAH) to form a $15 \mu\text{m}$ thick membrane.

Applying a voltage between the top and the bottom Cr electrode layers, a strain is produced in the ZnO film perpendicular to the film plane by inverse piezoelectric effect. The in-plane component of the strain causes in-plane strain to the FeSiB film, which controls the permeability of FeSiB film by the inverse magnetoelastic effect. The neutral plane of elastic strain is in the Si membrane. Positive applied voltage yields permeability decrease and negative voltage results in perme-

FIG. 4. Structure of micromagnetorestrictive-piezoelectric device.

FIG. 5. Time variation of permeability for piezoelectric type device.

FIG. 6. Permeability vs applied voltage relationship for piezoelectric type device.

FIG. 7. Structure of micromagnetorestrictive-electrostatic type device.

FIG. 8. Permeability vs applied voltage relationship for electrostatic type device.

FIG. 9. Time variation of permeability for electrostatic type device.

ability increase because the sign of piezoelectric constant, d_{31} , is negative as showed in Fig. 2. Figure 5 is the experimental verification that a 5 Hz, ± 30 V_{rms} ($\pm 2 \times 10^6$ V/m) sinusoidal voltage yielded the in-phase permeability change.

Theoretical permeability change is given by the following equation:

$$\mu_r' = M_s^2 / [\mu_0 \{2K_u - 3\lambda_s E(\Delta l/l)\}], \quad (1)$$

$$\Delta l/l = z/R, \quad (2)$$

where M_s is the saturation magnetization, K_u the anisotropy constant, E the Young's modulus, λ_s the saturation magnetostriction, z the distance from the neutral plane of elastic strain, and R the radius of film curvature. The film curvature and the position of neutral plane are determined by the thickness and Young's modulus of each of seven stacked film layer and the d_{31} of ZnO film.

Figure 6 shows the calculated permeability agrees with measured values but the rate of change was only 0.35%. This is because the permeability in micro structure is degraded from 1500 to 447 and the silicon membrane was as thick as 15 μ m. The rate of permeability change can be enhanced to 11% by removing the 15 μ m thick silicon membrane and also by improving the permeability from 450 to 1500.

IV. ELECTROSTATIC TYPE DEVICE

Figure 7 shows the schematic view of the magnetoelastic-electrostatic type microdevice. The 0.5 μ m thick FeSiB film was rf-sputter deposited onto a 50 μ m thick soda glass substrate and 0.4 μ m thick Au film for electrode was also deposited onto the opposite surface. This film-substrate was fixed over a grooved silicon wafer having a Au film electrode at the bottom of the groove. The groove is 40 μ m deep and formed by the 10% TMAH anisotropic wet-etching process. With applying a voltage between the two Au electrodes, attractive electrostatic force is generated and the FeSiB film feels tensile stress. Therefore, the permeability always increases regardless of the polarity of the applied voltage.

The generated electrostatic force f operates as a uniformly distributed load, w , and is proportional to the square of the applied voltage V ,

$$w = (f/l) = -(\epsilon_0 b/2)(V/d)^2. \quad (3)$$

When ϵ_0 is the permittivity of vacuum, b the beam width and d the beam thickness. Let the beam length be l , then the deflection y of the beam is given as follows.

$$y = -(w/24EI)x^2(l-x)^2, \quad (4)$$

where I is the geometrical moment of inertia and x the distance from the end of the beam along length direction. Then the radius R of beam curvature is given as $1/R = d^2y/dx^2$. Substituting R into (1) and (2), we obtain the permeability change.

The observed permeability change was in phase as the applied ac voltage and it roughly agreed with theory as shown in Fig. 8. The observed permeability change was 0.23% when 2 Hz, ± 77.5 V ($\pm 0.7 \times 10^6$ V/m) sinusoidal electric field was applied. The calculation above predicted that the permeability change can be improved to 80% if both the groove depth and the glass substrate are as thin as 20 μ m, respectively.

Time domain observation of the initial permeability was done using a figure-8 coil and a two-phase lock-in amplifier. Figure 9 shows the ac component of the initial permeability when a 2 Hz sinusoidal electric field is applied. The permeability varied at double the frequency of applied field because the strain due to the static field was always unidirectional.

V. CONCLUSION

A magnetostrictive-piezoelectric type micro device has been microfabricated using sputter deposited FeSiB amorphous magnetostrictive film with soft magnetic property and the ZnO piezoelectric film. Micromagnetostrictive-electrostatic type is also possible using the FeSiB film. The feasibility of these devices has been clarified although the rate of obtained permeability change was less than 1%. These device characteristics could be improved to 11% for piezoelectric type and to 80% for electrostatic type by the optimization of device dimensions and reduction of process damage to the magnetic film.

Nonlinear self-localized magnetoelastic surface waves in antiferromagnetic media

Igor E. Dikshtein^{a)}

Institute of Radioengineering and Electronics, RAS, Mokhovaya Street, 11, Moscow 103907, Russia

Sung-Ho Suck Salk

Department of Physics, Pohang University of Science and Technology, Pohang 790-784, Korea

Types of self-localized, magnetoelastic (ME) surface waves in antiferromagnets (AFs) are predicted, the existence of which is determined entirely by the nonlinear properties of the AFs. The frequency spectrum of the self-localized ME surface waves is shown to lie in a gap between the upper quasimagnon and lower quasiphonon branches of the harmonic ME spectrum. A nonlinear Schrödinger equation for the envelope of ME waves is derived and its solitonic solutions are obtained. When spin pinning or capillary effects on the surface of the crystal exist, we find that the nonlinear surface ME wave excites the volume ME wave at fundamental harmonics carrying energy into the interior of a crystal. © 1998 American Institute of Physics. [S0021-8979(98)52111-1]

Nonlinear magnetoelastic (ME) waves in an antiferromagnet (AF) possess a variety of distinguishing features that can be of great importance for magnetoacoustics.¹ Strong ME interaction is responsible for the giant effective anharmonicity of the elastic system ($\Delta C_3 \sim 10^3 - 10^4 C_2$ where $\Delta C_3 \sim C_3^{\text{eff}} - C_3$, C_2 , and C_3 are the second and third order elastic moduli, respectively).¹ The dispersion of ME waves increases considerably in the region of the magnetoacoustic resonance.²

It is easy to stimulate large amplitudes of surface ME waves at an AF surface. In such a case, nonlinear effects are especially important for surface ME wave propagation. The problem of the second ME harmonic generation³ and the effects of acoustic convolution in the nonlinear interaction of the Rayleigh surface ME waves^{4,5} was studied experimentally.

For the study of surface waves understanding of the interaction of a wave with other degrees of freedom in a system is essential. New types of linear surface waves can arise from such interaction. For example, the shear volume elastic wave in a ferromagnet transforms into a surface wave if ME coupling and dipole-dipole interaction are taken into account.⁶ The linear surface Rayleigh,⁷ Love,⁸ and Stonely⁹ waves can be damped out due to spin wave radiation into the interior of crystal.

In the present study we consider a new type of nonlinear surface ME waves in an AF that have no analogs to the case of linear waves and become delocalized with a zero amplitude. Nowadays the nonlinear self-localized surface waves of various kinds are well known in solids, e.g., the nonlinear surface acoustic waves,¹⁰ the nonlinear surface exchange spin waves,¹¹ and three-dimensional surface precession solitons.¹²

The system of present interest is a two-sublattice AF with weak ferromagnetism and an easy-plane-type anisotropy, occupying the half-space $z < 0$, in an external magnetic

field \mathbf{H} parallel to the surface ($\mathbf{H} \parallel \mathbf{x}$). The crystal axis perpendicular to the easy plane is directed along the z axis. In this case the free energy density of an AF is given by

$$F = F_m + F_{me} + F_e, \quad (1)$$

where

$$F_m = M_0 [H_E m^2 + H_A l_z^2 - 2H_D(\mathbf{m} \times \mathbf{l}) + \alpha M_0 (\partial V / \partial x_i)^2],$$

$$F_{me} = b M_0^2 l_i l_k u_{ik}, \quad F_e = (1/2) c_{iklm} u_{ik} u_{lm}$$

are the magnetic, ME, and elastic energy densities, respectively; H_E , H_A , and H_D are the exchange, anisotropy, and Moriya-Dzyaloshinsky fields; α , \hat{c} , and b are the nonuniform exchange, elastic, and ME constants; \hat{u} is the deformation tensor; $\mathbf{M}_{1,2}$ are the sublattice magnetizations ($|\mathbf{M}_1| = |\mathbf{M}_2| = M_0$); $\mathbf{L} = \mathbf{M}_1 - \mathbf{M}_2 = 2M_0 \mathbf{l}$ and $\mathbf{M} = \mathbf{M}_1 + \mathbf{M}_2 = 2M_0 \mathbf{m}$ are the ferromagnetic and AF vectors. For simplicity the AF is assumed to be ME and elastically isotropic. The inherent anharmonicity of the elastic lattice is neglected since it is not as important compared to the effective anharmonicity associated with ME coupling.¹ In an AF of a sufficient high Néel temperature $H_E \gg H_A$, H_D .¹ For the case of $H \ll H_E$, we note $m \ll l$ and $l^2 = 1 - m^2 \approx 1$.

The energy (1) is minimized for the ground state with $\mathbf{m}_0 \parallel \mathbf{x}$ and $\mathbf{l}_0 \parallel \mathbf{y}$ and $m_{0x} = (H_D + H)/H_E \ll l_{y0}$.

The nonlinear AF dynamics is described by the equations of motion²

$$\partial \mathbf{M}_n / \partial t = -g(\mathbf{M}_n \times \mathbf{H}_n^{(e)}), \quad \dot{\rho} \partial^2 u_i / \partial t^2 = \partial \sigma_{ik} / \partial x_k, \quad (2)$$

where $\mathbf{H}_n^{(e)} = -\partial F / \partial \mathbf{M}_n$ is the effective magnetic field, $\sigma_{ik} = \partial F / \partial u_{ik}$ is the tensor of the mechanical stresses, u_{ik} is the deformation tensor, g is the gyromagnetic ratio, and $n = 1, 2$ are the magnetic sublattice indexes.

The boundary conditions at the stress-free AF surface are

$$\sigma_{iz} = 0 \quad (i = x, y, z), \quad \mathbf{l} \times (\partial V / \partial \mathbf{z} + \beta_s \mathbf{l}) = 0, \quad (3)$$

with β_s the surface anisotropy constant.

FIG. 1. Classification of the roots characteristic of the characteristic equation (4). The noninteracting magnons and phonons are shown by dashed lines.

For a surface ME wave the decay conditions for \mathbf{l} and \mathbf{u} at $z \rightarrow -\infty$ are $|\mathbf{l}_x| \rightarrow 0$, $|\mathbf{u}| \rightarrow 0$.

It is easy to show that for an AF with sufficiently large easy-plane anisotropy [$H_A \gg H_{me} = b^2 M_0^2 / (2c_{44})$] $l_z \ll l_x$. Therefore, we assume $l_z = 0$ everywhere and do not take into account the high-frequency branch corresponding to vibrations involving a departure of \mathbf{l} from the basis plane.

Using the linear approximation of $\exp[i(ky - \omega t) + qz]$ for l_x and u_x , the characteristic equation for the ME waves is

$$(\omega^2 - \omega_{sk}^2 + V_m^2 q^2)(\omega^2 - \omega_{ik}^2 + S_t^2 q^2) - \omega_{me} \omega_E \omega_{ik}^2 = 0, \quad (4)$$

with V_m and S_t , the velocities of spin waves and the transverse sound,

$$\omega_{sk} = \sqrt{V_m^2 k^2 + \omega_H(\omega_H + \omega_D) + \omega_E \omega_{me}}, \quad \omega_{ik} = S_t k,$$

$$S_t = \sqrt{c_{44}/\rho},$$

$$\omega_E = gH_E, \quad \omega_H = gH, \quad \omega_D = gH_D, \quad \omega_{me} = gH_{me}.$$

Equation (4) has four roots q vanishing along curves $\omega = \omega_1(k)$ and $\omega = \omega_2(k)$, respectively,

$$\omega_{1,2}(k) = [\omega_{sk}^2 + \omega_{ik}^2 \mp \sqrt{(\omega_{sk}^2 - \omega_{ik}^2)^2 + 4\omega_E \omega_{me} \omega_{ik}^2}]^{1/2} / \sqrt{2}.$$

Figure 1 shows the behavior of the solutions of (4) on the plane (ω, k) for the low-temperature AF (MnCO_3 , CoCO_3 , CsMnF_3) with $T_N < T_D$ (T_N and T_D are the Néel and Debye temperatures, respectively) and $S_t > V_m$. The plane is divided into three regions. In region I [$\omega > \omega_2(k)$], and Eq. (4) has four imaginary roots. Volume ME waves correspond to region I. In region II [$\omega_1(k) < \omega < \omega_2(k)$], it has two real and two imaginary roots. In region III [$\omega < \omega_1(k)$], it has four real roots. The linear surface ME waves in region III and the linear leaky ME waves in region II can exist only when spin pinning and capillary effects on an AF surface are available.

The solutions of nonlinear equations (2) for the main harmonics of the upper branch of the ME waves have the form

$$l_x = (1/2)A(y, z, t) \exp i(ky - \omega_2 t) + c.c.; \quad (5)$$

$$u_x = (1/2)B(y, z, t) \exp i(ky - \omega_2 t) + c.c. \quad (6)$$

Here amplitudes A and B are the slowly varying envelopes to the rapid oscillations of the carrier waves,

$$\left| \frac{\partial G}{\partial t} \right| \ll \omega_2 |G|, \quad \left| \frac{\partial G}{\partial z} \right| \ll k |G|, \quad \left| \frac{\partial G}{\partial y} \right| \ll k |G|,$$

$$G = (A, B).$$

For weakly localized nonlinear surface ME waves of small amplitude the substitution of solutions (5) and (6) into (2) yields

$$i \left(\frac{\partial A}{\partial t} + v_{g2} \frac{\partial A}{\partial y} \right) + (1/2) D_2 \frac{\partial^2 A}{\partial z^2} + N_2 |A|^2 A = 0, \quad (7)$$

$$B = \gamma A [\gamma = -ikb\rho^{-1} M_0^2 / (\omega_{2k}^2 - \omega_{ik}^2)], \quad (8)$$

with the boundary conditions $\partial A / \partial z = \partial B / \partial z = 0$ for $\beta_s = 0$, where

$$v_{g2} = \Omega_2 k [S_t^2 (\Omega_{s2} + \omega_E \omega_{me}) + V_m^2 \Omega_{t2}], \quad D_2 = v_{g2} / k, \quad (9)$$

$$N_2 = \Omega_2 [\omega_E \omega_{me} \omega_{ik}^2 + \Omega_{t2} (4\omega_H^2 + 4\omega_E \omega_{me} + \omega_H \omega_D) / 16], \quad (10)$$

$\Omega_2 = [\omega_{2k}(\omega_{2k}^2 - \omega_{1k}^2)]^{-1}$, $\Omega_{s2} = \omega_{2k}^2 - \omega_{sk}^2$, and $\Omega_{t2} = \omega_{2k}^2 - \omega_{ik}^2$. In the present case of interest an AF is found to possess nonlinearity of the self-focusing type ($D_2 > 0$ and $N_2 > 0$).

From Eqs. (7) and (8) we get the nonlinear surface waves

$$l_x = (1/2)A_0 \text{sech}(z/z_0) \exp i[ky - (\omega_2 - 1/2T)t] + c.c.; \quad (11)$$

$$u_x = \gamma l_x, \quad T^{-1} = N_2 A_0^2, \quad z_0^{-1} = A_0 \sqrt{N_2 / D_2}, \quad (12)$$

where A_0 is the maximum envelope amplitude. A dispersion relation for nonlinear surface ME waves is then

$$\omega = \omega_2(k) - N_2 A_0^2 / 2. \quad (13)$$

The penetration depth of the surface ME wave is $z_0 \approx A_0^{-1}$ and tends to reach infinity as its amplitude decreases. When the frequency and the amplitude of waves are fixed, a wavelength of the nonlinear ME wave is smaller than that of the linear one.

According to the Lighthill criterion the nonlinear ME wave is modulationally unstable to create a train of solitary waves in the direction of propagation. It can give rise to formation of three-dimensional (3D) surface ME solitons. Such 3D surface solitons for spin waves were considered in Ref. 12.

A dispersion relation for a nonlinear volume surface ME wave that is uniform over the thickness of a crystal has the form

$$\omega = \omega_2(k) - N_2 A_0^2. \quad (14)$$

We now investigate the influence of surface spin pinning on the propagation of the nonlinear surface ME wave. In this case the boundary conditions (3) have the form

$$\partial u_x / \partial z = 0, \quad l_x (\partial l_y / \partial z + \beta_s l_y) - l_y \partial l_x / \partial z = 0. \quad (15)$$

In the present case solutions (11) and (12) from the nonlinear equations (2) do not satisfy the boundary conditions (15), owing to radiation of the energy of volume ME waves into the interior of the crystal.

For the purposes of illustration of the radiation effects we will consider the ME waves close to the upper quasimagnon branch ($\omega \leq \omega_{2k}$) in the range of small wave numbers k . In this limit the interaction between spin and elastic waves is weak. Substitution of Eqs. (11) and (12) (where the envelope amplitudes are the functions of z and index $2k$ is omitted for ω) into (2) yields

$$\frac{D_2}{2} \frac{\partial^2 A}{\partial z^2} + \frac{(\omega^2 - \omega_{sk}^2)A}{2\omega_{2k}} + N_2 A |A|^2 = \epsilon B, \quad (16)$$

$$\partial^2 B / \partial z^2 + Q^2 B = \epsilon_1 A. \quad (17)$$

Here $\epsilon = ikbgM_0\omega_E/(4\omega_{2k})$ and $\epsilon_1 = -ikbM_0^2/c_{44}$ are small values, $\omega_{2k} \approx \omega_{sk}$, $D_2 \approx V_m^2/\omega_{sk}$, $Q^2 = (\omega_{sk}^2 - \omega_{ik}^2)/S_i^2$, and the nonlinear term is ignored in (17). Inserting the unperturbed ($\epsilon = 0$) solution of (16): $A = A_0 \operatorname{sech}(z+Z)/z_0$ into (17), we can get

$$B = B_1 \exp(-iQz) - \frac{ikbAM_0^2}{Q^2 c_{44}} \operatorname{sech} \frac{z+Z}{z_0}, \quad (18)$$

where $A_0 = \sqrt{2(\omega_{sk} - \omega)/N_2}$ and $z_0 = \sqrt{D_2/[2(\omega_{sk} - \omega)]}$. A shift Z is obtained from the first boundary condition (15) as $Z = -z_0 \tanh^{-1}(\beta_s z_0)$. The amplitude of the outgoing ME wave $B_1 \propto \beta_s b A_0$ is determined from the second boundary condition (15).

It follows from (18) that the nonlinear surface ME wave excites volume ME waves at the frequency of the fundamental wave carrying energy into the interior of a crystal. Therefore, there is no energy localization of nonlinear surface ME waves, and they are, in fact, quasisurface waves. The effect results solely from the ME interaction. For $b = 0$ there is no radiation of energy from the surface ($B_1 = 0$).

In the case $\beta_s < 0$, the amplitude maximum of the nonlinear surface ME wave, is shifted into the interior of the crystal. In this case the "repulsion" of the surface ME wave from the surface is compensated for by nonlinear "attraction." Such a wave can be detached from the surface to become a volume soliton. For $\beta_s > 0$ the amplitude is maximal on the AF surface.

The characteristic damping time of the surface ME wave can be evaluated from

$$T_d \approx E/(\partial E/\partial t) \propto \beta_s^{-2} A_0^{-1}, \quad (19)$$

where $E = \int_{-\infty}^0 F dz \propto A_0$ is the energy density and $\partial E/\partial t = -c_{44}(\partial u_x/\partial t)(\partial u_x/\partial z) \propto \beta_s^2 A_0^2$ is the energy flux density of the nonlinear surface ME wave per unit surface area. Therefore, the characteristic distance $L_d = V_{g2} T_d$ for the propagation of surface ME waves during $T_d \propto \beta_s^{-2} A_0^{-1}$ is large for the small amplitude wave.

It is easy to show that close to the lower quasiphonon branch of a ME spectrum an AF possesses nonlinearity of the defocusing type ($N_1 < 0$, $D_1 > 0$) and nonlinear, self-localized surface ME waves do not exist for the free boundary conditions ($\beta_s = 0$).

In conclusion, we have demonstrated that ME waves in an AF can be localized near the surface due to nonlinearity of the crystal. In contrast to the linear case nonlinear quasisurface waves can exist for both positive and negative signs of surface anisotropy constants. Nonlinear surface and quasisurface waves are expected to occur in other interacting systems involving different kinds of waves, e.g., the acoustic and optic waves in ferroelectrics and the spin and electromagnetic waves in ferromagnets.

The Re-doped high T_c superconductor $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_x$: Magnetic irreversibility versus anisotropy

L. Fàbrega, B. Martínez, J. Fontcuberta, A. Sin, S. Piñol, and X. Obradors
Institut de Ciència de Materials (CSIC), Campus de la U.A.B., 08193 Bellaterra, Spain

We report on magnetization measurements on grain-aligned Re-doped Hg-1223 superconductor ($T_c \approx 133$ K). We analyze the anisotropic magnetic hysteresis M_{irr} as a function of temperature and magnetic field, and determine the irreversibility line $H_{\text{irr}}(T)$ for magnetic fields applied parallel and perpendicular to the c axis of the structure. The similar values of both M_{irr} and $H_{\text{irr}}(T)$ along the two main crystallographic directions reveal a marked decrease of the superconducting anisotropy, due to the Re substitution. This anisotropy reduction might be at the origin of the rise of the magnetic irreversibility already reported in these compounds, as compared to those without Re. © 1998 American Institute of Physics. [S0021-8979(98)42511-8]

I. INTRODUCTION

The copper oxide $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_x$ is the superconductor with the highest T_c (≈ 134 K) reported to the date.¹ However, it has been rather poorly characterized, because of its difficult synthesis (requiring high pressure) and its reported high anisotropy. It is well known that superconducting copper oxides with extreme anisotropy have important disadvantages for their use in applications, because magnetic flux moves very easily in them, and therefore they are unable to carry high electrical currents, without dissipation, in most of their H - T phase diagram.

An important step forward was realized when it was shown² that the partial substitution of Hg by Re stabilizes the phase, allowing its synthesis without application of high pressure. Furthermore, this substitution does not lower T_c and rises the irreversibility line of the superconductor,²⁻⁵ i.e., broadens the nondissipative region of its H - T phase diagram.

These important issues—particularly the last result, which was soon attributed to a decrease of the anisotropy^{5,6}—have awakened the interest for this material. Indeed, from the above considerations, the relevance of having a superconductor with very high critical temperature and reduced anisotropy may be clearly presumed. Therefore, to determine the anisotropic irreversibility line of this superconductor and establish the effect of the Re have become a matter of the greatest interest, and are the object of this article.

We report on magnetic hysteresis measurements of grain-aligned $\text{Hg}_{0.82}\text{Re}_{0.18}\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_{8+\delta}$ for both $H//ab$ and $H//c$. These data were analyzed in order to extract the anisotropic magnetic irreversibility, as well as the irreversibility line along the two main crystal directions, and therefore get an insight into the effective anisotropy of these Re-doped superconductors. The results reveal a huge anisotropy decrease, which should modify both the bulk pinning and surface barrier effects of the superconductor. We discuss this

feature and try to correlate it to the already reported enhancement of magnetic irreversibility due to the Re substitution.

II. EXPERIMENT

Ceramic $\text{Hg}_{0.82}\text{Re}_{0.18}\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_{8+\delta}$ was synthesized following the procedure described in Ref. 7. The as-prepared material, with $T_c \approx 133$ K, was powdered, dispersed in an insulating epoxy down to a volume concentration of 3%, and oriented by using a high magnetic field. The superconducting grains, which may be considered as isolated, are platelets of average width 3 μm and thickness 0.5 μm .

The x-ray diffractograms (Fig. 1) confirmed the good orientation of the superconducting grains, showing mainly the (0 0 1) peaks; only some traces of other reflections could be detected. The c -axis spread is $\Delta\theta \approx 3.5^\circ$ [full width at half maximum of the rocking curve of the (0 0 6) peak].

DC magnetization was measured for $H//c$ and $H//ab$ with a Quantum Design superconducting quantum interference device magnetometer, as a function of temperature and magnetic field ($H < 55$ kOe). The samples used in these measurements are bars with typical dimensions $2 \times 2 \times 5$ mm³, the longest one being either parallel or perpendicular to the c -axis direction.

FIG. 1. θ - 2θ diffractogram of a grain-oriented sample. Inset: rocking curve of the (006) peak.

FIG. 2. Hysteresis cycles measured at 5, 20, and 40 K, for $H//ab$ and $H//c$.

III. RESULTS AND DISCUSSION

Figure 2 shows the hysteresis cycles for the field applied along the two main crystal directions, at $T=5, 20$, and 40 K. The different slopes of the overall $M(H)$ at high fields are due to the background contribution of the epoxy used to orient the samples. A strong decrease of the superconductor hysteresis width with temperature is appreciated. Also, at the lower temperatures the ascending and descending field branches are quite symmetric, indicating that bulk pinning is responsible for the observed magnetic irreversibility. As temperature increases and approaches 40 K, the hysteresis cycles lose their symmetric character, denoting a strong reduction of bulk pinning. Surface barriers then become the main contribution to the magnetic irreversibility of these superconductors, as revealed by the field return branch becoming increasingly flat, with magnetization values close to zero.⁸ The crossover from bulk pinning to surface barrier irreversibility for $H//c$ has been carefully analyzed in Ref. 9, where it was shown that bulk pinning remains observable up to 40 K.

Dominant contributions of surface barriers to the magnetic irreversibility have been earlier reported for several Hg-based compounds, with and without Re.^{6,10} Our results, however, reveal an important difference. For the Hg phases without Re, surface barriers seem to dominate in most of the $H-T$ phase diagram; bulk pinning is almost unobservable in these materials at temperatures above 15 K.¹⁰ Yamasaki *et al.* also report surface barrier irreversibility down to 30 K for a grain aligned sample with 10% Re. In our samples, with 18% Re, bulk pinning is still observable at 40 K. Comparison of the aforementioned results suggests thus an enhancement of the low temperature flux pinning as the Re content increases.

Figure 3 shows the field dependence of the irreversible magnetization $M_{irr} = |M_{\uparrow} - M_{\downarrow}|/2$ for $H//c$ and $H//ab$, at 20 and 40 K. We appreciate that, in agreement with the above arguments, the hysteresis width at 20 K is about a factor of 5 larger than that observed in Ref. 10 at 15 K, for a sample without Re. The critical currents extracted from our M_{irr} data by using the critical state model displays in fact quite high values; the critical current along the planes $J_c^{ab;H//c}$ lies

FIG. 3. $M_{irr}(H)$ at $T=20$ and 40 K, for $H//ab$ and $H//c$.

above 10^6 A/cm² at 5 K and 3 T. However, bulk pinning displays a strong decay with temperature and field, which is responsible for the dominant contribution of surface barriers to M_{irr} at $T > 40$ K.⁹ The same feature is observed for the unsubstituted samples, although at much lower temperatures. Therefore, the improvement of bulk pinning by Re, though significant, is not as yet sufficient to make these materials interesting for applications at high temperatures or fields.

We move now to another remarkable feature revealed by Figs. 2 and 3; this is the similarity of the magnetic irreversibility values—as well as their temperature and field dependences—for the field applied along the two main crystal directions of the superconductor. At low temperatures, $M_{irr}^{H//c}$ is at most a factor of 3 larger than $M_{irr}^{H//ab}$. As H increases, this difference is even lower, due to the stronger decay of $M_{irr}^{H//c}$ with field. In fact, the $M_{irr}(H)$ curves cross each other at high enough temperatures, as clearly appreciated in Fig. 3 for $T=40$ K.

The close values of $M_{irr}^{H//c}$ and $M_{irr}^{H//ab}$ point to a very moderate value of the anisotropy in these materials. In fact, analyses of the high field reversible magnetization performed on the same grain-aligned samples,¹¹ reveal a very low anisotropy ratio $\gamma = m_c/m_{ab} \approx 5$. Yamasaki *et al.*⁶ have also reported $\gamma \approx 8$ from equivalent analyses on samples with 10% Re. Such low values are to be compared with $\gamma \approx 50$, reported for a Hg-1223 single crystal.¹² These recent works reveal therefore a huge anisotropy reduction induced by the Re; such a huge effect is outstanding, even though it had already been pointed out, as a consequence of the metallization of the interlayers. Evidences for this metallization, which would be due to the metallic character of ReO_3 , have been claimed to exist upon comparison of μSR data for these and other high temperature superconductors.⁵

We would like to stress that a misorientation of the applied field with regard to the main crystal directions cannot account for the similarity of the data for $H//c$ and $H//ab$, shown in Figs. 2 and 3. Indeed, unrealistic misorientation angles of about 45° should be considered in order to accommodate the $M(H)$ data to the picture of a highly anisotropic superconductor in which only $H//c$ contributes to M . Note, for instance, that the magnetization minima, denoting the full

FIG. 4. Irreversibility line extracted from Zero Field Cooling/Field Cooling $M(T)$ data, for $H//ab$ and $H//c$.

penetration of the sample by the applied field, occur at similar values for both field orientations, at any temperature.

On the other hand, we have verified that demagnetization effects are not important by performing $M(H)$ measurements for both orientations of the external field using samples with the long dimension parallel and perpendicular to the field; these measurements, which turn out to depend only on the orientation of H regarding the crystal axes, have allowed to rule out any sample shape effect.

The low anisotropy of this material is further confirmed by the irreversibility lines for $H//ab$ and $H//c$, which are shown in Fig. 4, for $\mu_0 H < 2$ T. They have been obtained from the merging point of the Zero Field Cooling and Field Cooling $M(T)$ curves; at higher fields, both branches of the $M(T)$ data approach each other asymptotically and it becomes extremely difficult to define T_{irr} . We see in Fig. 4 that, for the low field/high temperature range explored, both irreversibility lines are almost coincident. Similar conclusions may be drawn from preliminary AC susceptibility data analyses. We would like to remind here that, in this region of the H - T phase diagram, magnetic irreversibility is governed by surface barriers.⁹ The likeliness of both $H_{irr}(T)$ lines points, therefore, to a quite isotropic surface barrier contribution, giving further support to the already discussed low anisotropy of these compounds.

The Re substitution appears thus to influence both bulk pinning and surface barriers. The observed effects seem to be mainly related to the induced anisotropy reduction, which would imply a change of the superconductor dimensionality, from two-dimensional to three-dimensional. As already discussed, a reduction of the anisotropy γ would result in an increase of the vortex lines stiffness, which would lead to an enhancement of flux pinning, as observed at low temperatures. At the same time, lower γ values would result in an

increase of the full penetration and irreversibility fields due to surface barriers, as shown in Ref. 9. However, other contributions to the irreversibility, as Re originated microstructural changes, might also be relevant.

In conclusion, we have shown that the magnetic irreversibility of Re-substituted Hg-1223 superconductors is larger than that of the unsubstituted compounds. We have presented evidence that at low temperatures this increase is due to a significant improvement of bulk pinning, which overcomes the surface barrier contribution up to 40 K. At higher temperatures, surface barriers dominate the irreversible magnetization, as it happens in the unsubstituted samples. The anisotropic magnetic hysteresis, determined from the hysteresis cycles at low temperatures, reveals a very moderate value of the anisotropy. Such a surprising effect of the Re-substitution is likely due to the reduction of the distance between superconducting Cu-O planes and the metallization of the interlayers because of the presence of ReO_3 . Both effects might lead to the existence of proximity induced superconductivity in the interlayers, and therefore account for the low γ value, which in fact is the lowest reported for high- T_c ($T_c > 77$ K) superconducting cuprates. Further studies of the anisotropy and pinning in these materials become thus compelling, since they might be extraordinary interesting for applications.

We have investigated the $\text{RSr}_2\text{Fe}_3\text{O}_9$ ($\text{R}=\text{La}$, Y , Pr , and Gd) materials by several experimental techniques, including x-ray and neutron diffraction, magnetic susceptibility, and Mossbauer spectroscopy measurements. All materials studied are single phase and crystallize in the hexagonal perovskite structure. Magnetic susceptibility studies reveal that, for $\text{R}=\text{La}$ and Pr , the Fe ions order antiferromagnetically at about $T_N=190$ K. Short range magnetic correlations are observed up to 250 K. For $\text{R}=\text{La}$ and Pr , ^{57}Fe Mossbauer studies reveal two inequivalent magnetic sextets below 190 K, with the area ratio 2:1. Above T_N , one singlet is observed with an isomer shift value typical to Fe^{4+} . For $\text{R}=\text{Y}$ and Gd , the magnetization curves do not lend themselves to easy determination of the magnetic transition due to an extra magnetic phase which exists up to 350 K. This phase is a result of deficiency of oxygen. The ^{57}Fe Mossbauer spectra at 300 K indicate two superimposed singlet lines, and contain a small magnetic sextet. There is no indication that the R sublattice in $\text{RSr}_2\text{Fe}_3\text{O}_9$ ($\text{R}=\text{Pr}$ and Gd) orders magnetically down to 1.5 K. © 1998 American Institute of Physics. I. INTRODUCTION

Discovery of high T_c superconductivity (HTSc), above 90 K in (rare earth) R based oxygen deficient perovskite cuprates $\text{RBa}_2\text{Cu}_3\text{O}_7$ ($\text{R}:\text{123}$) has provoked considerable interest in superconductivity and magnetism of various R based perovskites.^{1,2} In principle, R:123 type compounds can be obtained with Ba replaced by Sr and Cu replaced by Fe.^{3,4} Fe based oxides ($\text{RBa}_2\text{Fe}_3\text{O}_8$ and $\text{RSr}_2\text{Fe}_3\text{O}_8$) are not superconducting.³⁻⁵ There are reports of structural magnetic and thermal measurements on some members of the series $\text{RBa}_2\text{Fe}_3\text{O}_8$ (RBFO).³⁻⁷ Also a unique behavior of $\text{PrBa}_2\text{Fe}_3\text{O}_8$ (PBFO), in terms of magnetic and thermal properties was observed in comparison to other R counter parts of the same formula.^{8,9} RBFO compounds are more or less widely explored until now.³⁻⁹ On the other hand for $\text{RSr}_2\text{Fe}_3\text{O}_9$ (RSFO), while the structural details are available for most of R members,¹⁰ detailed magnetic measurements were reported recently only for $\text{LaSr}_2\text{Fe}_3\text{O}_9$ (LSFO).¹¹

In present the article we report details of the structural and magnetic properties of RSFO compounds with $\text{R}=\text{Y}$, La , Pr , and Gd . Details of neutron diffraction, magnetic measurements, and Mossbauer spectroscopy are to be presented.

II. EXPERIMENT

The samples of RSFO with $\text{R}=\text{Y}$, La , Pr , and Gd were synthesized through a solid state reaction route with ingredients of Y_2O_3 , La_2O_3 , Pr_6O_{11} , Gd_2O_3 , SrCO_3 , and Fe_3O_4 . The samples were calcined and reground several times at temperatures of 950, 1000, 1050, 1100, 1150, 1200, 1250, 1300, 1350, and 1400 °C, for 24 h at each temperature, to ensure the formation of single phase compounds. The samples were further annealed at 1000 °C for 48 h in flowing oxygen and were subsequently cooled to room temperature in the same gas atmosphere over a span of 10 h. Neutron diffraction patterns were obtained at room temperature on the powder diffractometer at the Missouri University Research Reactor Centre, with neutrons of wavelength 1.7675 Å. The dc magnetic measurements on solid ceramic pieces in the range of 2–300 K were performed in a commercial (Quantum Design) superconducting quantum interface device (SQUID) magnetometer. The magnetization was measured by two different procedures. (a) The sample was zero field cooled (ZFC) to 5 K, a field was applied and the magnetization was measured as a function of temperature. (b) The sample was field cooled (FC) from above 300 to 5 K and the magnetization was measured. The Mossbauer spectroscopic studies (MS) were carried out using a conventional

constant acceleration spectrometer. The ^{57}Fe MS were measured with a 50 mCi $^{57}\text{Co}:\text{Rh}$ source and the isomer shift (IS) are reported with respect to metallic Fe.

III. RESULTS AND DISCUSSION

A. Neutron diffraction

Figure 1, depicts the observed and fitted neutron diffraction patterns for RSFO samples with $\text{R}=\text{La}$ and Pr . As evident from this figure, the samples are single phase with no impurity lines in the neutron patterns. All the samples of series RSFO with $\text{R}=\text{Y}$, La , Pr , and Gd crystallize in the Rhombohedral structure ($a=b\neq c$, $\alpha=90^\circ$, $\beta=90^\circ$, and $\gamma=120^\circ$) with space group $R3c$. Earlier a cubic structure was proposed for the LSFO compound,^{4,5} but later it was observed that nearly all R with formula RSFO are better fitted in a hexagonal structure.¹⁰ The same is true for our samples also, where we observed a very good fit to the observed patterns with a $R3c$ hexagonal structure, see Fig. 1. The a , b , and c lattice parameters for various samples of RSFO series are as follows:

$\text{YSr}_2\text{Fe}_3\text{O}_9$

$$a=b=5.4664(7) \text{ \AA}, \quad c=13.3793(34) \text{ \AA},$$

$\text{LaSr}_2\text{Fe}_3\text{O}_9$

$$a=b=5.4883(7) \text{ \AA}, \quad c=13.4331(31) \text{ \AA},$$

$\text{PrSr}_2\text{Fe}_3\text{O}_9$

$$a=b=5.47601(15) \text{ \AA}, \quad c=13.3819(7) \text{ \AA},$$

and $\text{GdSr}_2\text{Fe}_3\text{O}_9$

FIG. 2. Temperature dependence of the susceptibility for $\text{PrSr}_2\text{Fe}_3\text{O}_9$ measured at 20 Oe, and the ZFC branch in inset. Note that the ZFC and FC branches merge at 260 K.

$$a=b=5.4668(9) \text{ \AA}, \quad c=13.3798(19) \text{ \AA}.$$

Our values of a , b , and c -lattice parameters for various samples, studied presently are comparable to those reported earlier.¹⁰ These values of lattice parameters also follow the ionic radius difference of the Y, La, Pr, and Gd. Lowest ionic size Y and Gd, are followed by relatively bigger ions La and Pr with increasing c -lattice parameters.

B. Magnetic behavior

The ZFC and FC magnetic susceptibility, measured at 20 Oe of $\text{PrSr}_2\text{Fe}_3\text{O}_9$ (PSFO) is shown in Fig. 2. Generally speaking, in both branches, only one distinct anomaly is observed. In analogy to $\text{PrBa}_2\text{Cu}_3\text{O}_7$,¹² it is possible that the Pr sublattice is magnetically ordered at low temperatures, but this ordering is not visible in the curves. We tend to believe that the anomalies in these branches are related to the Fe sites. The Neel temperature, $T_N(\text{Fe})$ is 195(1) K and is defined as the peak in the ZFC branch (Fig. 2 inset), which is above the sharp decrease position of the FC branch. Within the limit of uncertainty the same $T_N(\text{Fe})$ is obtained for La containing compound. It appears that T_N of Fe is about 200 K for all R, apparently independent of whether the trivalent R ions are magnetic (Pr, Fe) or not (Y, La). It is worth mentioning here that in RBFO compounds, the PBFO showed a unique behavior in terms of Fe ordering temperature.^{8,9} Particularly Fe moment orders around 700 K for all studied RBFO compounds, except PBFO, for which the same happens at around 290 K. The nearly linear (at high applied field) field dependence of the magnetization at 5 K (not shown), suggests that Fe sublattice order antiferromagnetically (AFM). The irreversibility probably arises from this AFM alignment of the Fe sublattice. It is assumed that in the FC process the external field causes the spins to cant slightly out of their original direction. This canting abruptly aligns a component of the moments with the direction of the field, and the FC branch is obtained. The effect of field strength on the irreversibility is significant. At low applied fields, the

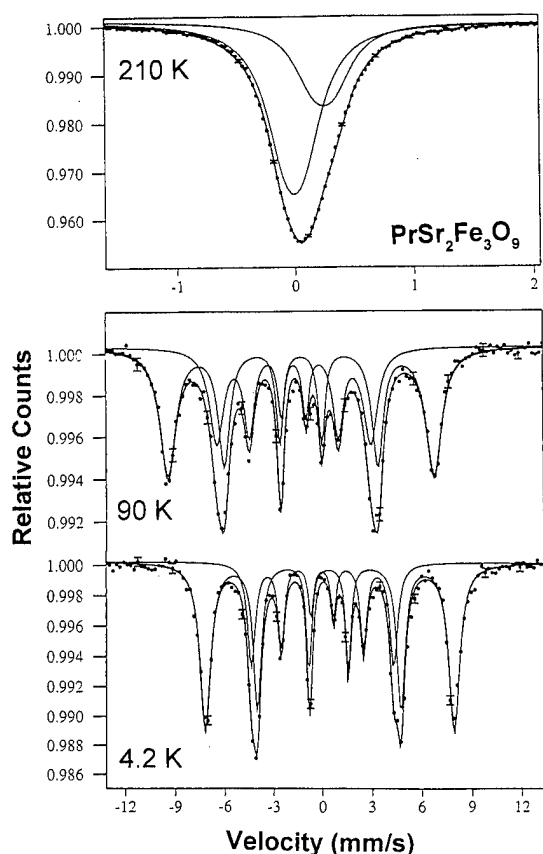

FIG. 3. Mossbauer spectra of $\text{PrSr}_2\text{Fe}_3\text{O}_9$ in the paramagnetic state (210 K) and below $T_N(\text{Fe})$. The solid curves are theoretical least square fits in terms of 2 subspectra corresponding to inequivalent Fe sites.

field dependence of the magnetization is not linear, and the fact that the ZFC and FC curves merge at 260 K [above $T_N(\text{Fe})$], indicated the existence of an internal magnetic field at low temperatures, which vanishes at 260 K. The magnetic results, shown in Fig. 2, confirm our Mossbauer (MS) studies, which are displayed and discussed in the next section.

C. Mossbauer spectroscopy

Mossbauer spectrum of ^{57}Fe in $\text{PrSr}_2\text{Fe}_3\text{O}_9$ (PSFO) at 210 K [above $T_N(\text{Fe})$] is shown in Fig. 3. The main information obtained from visual and computer analysis is the presence of two subspectra corresponding to inequivalent Fe sites, which are immediately identified from their hyperfine parameters: the isomer shift (IS) and quadrupole splitting ($\Delta = 1/4e^2qQ$) values, with a common line width of 0.40(2) mm/s. The *dominant* line which accounts for 66% of the spectra area, has a small IS = -0.11 mm/s and a Δ of 0.06(1) mm/s and can be assigned as Fe^{4+} in the low spin state. Both, the IS = 0.17 and $\Delta = 0.07$ mm/s of the *minor* doublet (33%), are typical to Fe^{3+} . For $\text{R}=\text{La}$, the MS measured at various temperatures (not shown) are very similar to the spectra shown in Fig. 3, proving the Pr ions are trivalent.

In fitting the experimental parameters below $T_N(\text{Fe})$, the iron in $\text{PrSr}_2\text{Fe}_3\text{O}_9$ (and for $\text{R}=\text{La}$), is composed of *predomi-*

nantly Fe^{3+} (66% at 4.2 K), Fe^{5+} (33% at 4.2 K), and an increasing fraction with temperature of Fe^{4+} (zero at 4.2 K). The 4.2 K spectrum (Fig. 3) is composed of two magnetic subspectra with IS = 0.37 and -0.03 , an effective magnetic hyperfine field: $H_{\text{eff}} = 469(3)$ and $269(2)$ kOe (the effective quadrupole splitting is zero for both sites), corresponding to Fe^{3+} and Fe^{6+} , respectively. These hyperfine parameters are consistent with this assignment. The spectrum at 90 K (Fig. 3) is fitted in the same manner. It thus assumed, that the nonmagnetic Fe^{4+} ions fraction increases with temperature and dilutes the magnetic Fe^{3+} and Fe^{5+} ions. At $T_N(\text{Fe})$, (the Fe^{4+} fraction becomes 66%) the magnetic order disappears.

IV. CONCLUSIONS

In conclusion we assume below $T_N(\text{Fe})$, the presence of Fe^{5+} (33% at 4.2 K, lowest IS and small H_{eff}) and Fe^{3+} (66% at 4.2 K, highest IS and large H_{eff}), and Fe^{4+} (0% at 4.2 K, intermediate IS and no H_{eff}). Whereas, at high temperatures [above $T_N(\text{Fe})$], most of the Fe ions are in nonmagnetic Fe^{4+} state. The valance fluctuations occur only as a single electron process: $\text{Fe}^{5+} \rightarrow \text{Fe}^{4+}$ and $\text{Fe}^{3+} \rightarrow \text{Fe}^{4+}$.

In summary all the samples of series $\text{RSr}_2\text{Fe}_3\text{O}_9$ with $\text{R}=\text{Y}$, La, Pr, and Gd crystallize in hexagonal $\text{R}\bar{3}c$ structure. Also their magnetic properties are very similar to each other. $\text{PrSr}_2\text{Fe}_3\text{O}_9$ behaves magnetically in a similar way as other $\text{RSr}_2\text{Fe}_3\text{O}_9$ compounds, unlike the case of $\text{PrBa}_2\text{Cu}_3\text{O}_7$ and $\text{PrBa}_2\text{Fe}_3\text{O}_8$, which are reported to have unique behavior.^{8,9,12}

We report the results on structural aspects, magnetic, and superconducting properties of the $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ system. Both x-ray and neutron diffraction studies reveal that Pr substitutes isostructurally in the tetragonal $\text{LaBaCaCu}_3\text{O}_7$ (La:1113) system until the complete replacement of La by Pr. The superconducting transition temperature, T_c , determined from ac susceptibility measurements decreases, with increasing x . The relative T_c depression due to Pr in the $\text{LaBaCaCu}_3\text{O}_7$ superconductor is less in comparison to that found for La-site Pr substituted $\text{LaBa}_2\text{Cu}_3\text{O}_7$ (La:123). While the critical Pr concentration (x_{cr}) to completely suppress the superconductivity in the former is around 70 at. % of Pr at La site, the same is reported as only 30 at. % for the latter. For nonsuperconducting samples, i.e., for $x=0.70$ and 1.0, possible antiferromagnetic ordering with Neel temperatures, T_N , of 4 and 8 K, respectively, are observed from both dc magnetic and heat capacity measurements. Interestingly in the $\text{La}_{1-x}\text{Pr}_x$:1113 system the x_{cr} of Pr is 0.70, and T_N of Pr:1113 is 8 K, while for the $\text{La}_{1-x}\text{Pr}_x$:123 system x_{cr} is 0.30 and T_N of Pr:123 is 17 K. The results are explained on the basis of distribution of Pr at both RE and Ba sites in the RE:1113 structure. This leads to a lower T_N and a less deleterious effect of Pr on superconductivity of La:1113 compared to La:123. © 1998 American Institute of Physics. [S0021-8979(98)17411-X]

I. INTRODUCTION

High temperature superconductivity (HTSc) above 90 K is observed in nearly all RE (rare earth) based $\text{REBa}_2\text{Cu}_3\text{O}_7$ (RE:123) compounds, except Ce, Pr, and Tb.¹ The structure of RE based 123 perovskite compound consists of two dimensional Cu–O planes and one dimensional Cu–O chains embedded between Ba and RE layers.² Both Ce and Tb based RE:123 compounds do not crystallize in the required structure: instead they form a multiphase system.³ The situation is more interesting in the case of Pr:123 ($\text{PrBa}_2\text{Cu}_3\text{O}_7$). This compound crystallizes in ideal orthorhombic RE:123 structure, similar to that of other superconducting compounds of this family, yet with no superconductivity.^{4–15} In fact, $\text{PrBa}_2\text{Cu}_3\text{O}_7$ is an antiferromagnetic insulator, with Cu spins in CuO_2 planes ordered near room temperature and Pr moments ordered at nearly 17 K.¹⁵ However, as far as we know, three reports exist in literature which claim superconductivity of Pr:123: one on laser ablated $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{Ba}_2\text{Cu}_3\text{O}_7$ thin film,⁶ another on bulk $\text{Pr}_{1-x}\text{Ca}_x\text{Sr}_2\text{Cu}_{2.7}\text{Mo}_{0.3}\text{O}_7$ and one on recently reported $\text{PrBa}_2\text{Cu}_3\text{O}_7$ single crystals.⁸ Unfortunately, none of these results have been confirmed till now. The most promising one is the latest⁸ by Zou *et al.* [Jpn. J. Appl. Phys., Part 2 36, L18 (1997)]. These authors show bulk superconductivity of 80 K for $\text{PrBa}_2\text{Cu}_3\text{O}_7$ single crystals. These results have been greeted with considerable criti-

cism since the structure of superconducting Pr:123 compound reveals an anomalously long c axis questioning whether this material is truly isostructural with the superconducting RE:123 materials. Moreover, like other reports on superconducting Pr:123 compounds,^{6,7} the latest one,⁸ also lacks the universal reproduction of the same by other groups.

There are several models in the literature which try to explain the nonobservation of superconductivity in $\text{PrBa}_2\text{Cu}_3\text{O}_7$. The most widely discussed are the hole filling model,^{4,9,10} and pair breaking mediated by the hybridization of Pr 4*f* with O 2*p* states.^{11,12} The hole filling model is based on the existence of Pr in a valence state of more than +3, and whereby the extra electrons from Pr neutralizes mobile holes and brings the compound to near insulating regime. This model also accounts for the restoration of superconductivity in $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{Ba}_2\text{Cu}_3\text{O}_7$, where the holes are restored by lower valence Ca substitution at Pr site in the compound.⁶ The main drawback of this model is that a valence state of more than 3+ could never be detected in the $\text{PrBa}_2\text{Cu}_3\text{O}_7$ compound. In fact the detailed magnetic susceptibility,^{13,14} photoemission spectroscopy,¹⁵ x-ray absorption,¹⁶ and electron energy loss spectroscopy¹⁷ results altogether favor a +3 valence state of Pr in $\text{PrBa}_2\text{Cu}_3\text{O}_7$.

While the pair breaking model appeared to be promising, in that it could explain the suppression of superconductivity

in $\text{RE}_{1-x}\text{Pr}_x:123$ systems,^{11,12} pair breaking itself could not account for the insulating behavior of the $\text{PrBa}_2\text{Cu}_3\text{O}_7$ compound.

Two more recent and better understood models are given by Fehrenbacher and Rice (FR) and Liechtenstein and Mazin (LM).^{18,19} Both models involve the transfer of holes from superconducting $p d \sigma$ state to the $p d \pi$ state. In the FR model, the $p \pi$ orbitals of the planar oxygens neighboring a Pr ion, form a hybrid with the $\text{Pr-}f_{z(x^2-y^2)}$ orbital, which is strongly localized.¹⁸ Further in this model, the $p \pi$ holes are predominantly planar (p_{xy}), according to LM,¹⁹ the same have comparable amounts of $p_{x,y}$ and p_z character. The FR and LM models could also gain credence from recent x-ray absorption spectroscopy results on the $\text{Y}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$ system.²⁰ Although both the FR and LM models explain the insulating behavior of $\text{PrBa}_2\text{Cu}_3\text{O}_7$, they do not successfully account for the T_N of nearly 17 K for Pr moments in this compound.

With more and more experimental results appearing in the literature the mystery of nonsuperconducting $\text{PrBa}_2\text{Cu}_3\text{O}_7$ is becoming increasingly complicated. In the present study we report an interesting result on two different types of Pr doped RE:123 compounds, with the same rare earth, La. These results suggest that both T_c suppression and the antiferromagnetic ordering of Pr moments are closely related to each other. We study the compound $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ with several x values and compare the same with reported data²¹ on $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$. Our structural, magnetic and thermal measurements on this system show that the critical concentration of Pr (x_{cr}) to quench superconductivity in this system is 0.70 which is double of that found earlier for $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$ ($x_{cr}=0.30$).

II. EXPERIMENT

Samples of the series $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$, with $x=0.0, 0.10, 0.20, 0.30, 0.40, 0.50, 0.60$, and 1.0, were prepared by a solid state reaction from La_2O_3 , BaCO_3 , CaCO_3 , Pr_6O_{11} , and CuO each of 4N purity with the procedure, as reported in Ref. 22. The samples were characterized for their phase purity by x-ray diffraction (XRD) measurements. Alternating current magnetic susceptibility measurements were carried out on a Quantum Design SQUID magnetometer, in an applied r.m.s. field of 0.01 mT and 31 Hz. Neutron diffraction patterns at room temperature were obtained for the samples with $x=0.0$ and 1.0 using the research reactor facility of the University of Missouri. The experimental details are similar to those reported earlier for RE:123 ceramic samples.²³

III. RESULTS AND DISCUSSION

X-ray diffraction studies show that $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ samples are nearly single phase materials. All the samples crystallize in a P4/mmm tetragonal RE:123 phase with a decrease in the c parameter with increasing x .²² The $\text{LaBaCaCu}_3\text{O}_7$ compound is known to crystallize in the tetragonal RE:123 structure, despite having an oxygen content close to 7.0, due to the intermixing of La, Ba, and Ca sites which gives rise to equally occupied O(1) and O(5) sites in CuO chains, resulting in $a=b$.^{24,25}

FIG. 1. Fitted and observed Neutron diffraction patterns for $\text{LaBaCaCu}_3\text{O}_7$ and $\text{PrBaCaCu}_3\text{O}_7$ samples, taken at room temperature.

Room temperature observed and fitted neutron diffractions patterns for $\text{PrBaCaCu}_3\text{O}_7$ and $\text{LaBaCaCu}_3\text{O}_7$ compounds are shown in Fig. 1. In addition to the lines from main phase, both the samples show a few diffraction lines from unreacted species in their respective spectra, similar to those observed earlier in x-ray diffraction patterns of these compounds.^{22,26} The results of the Rietveld refinement procedure using the Generalized Structural Analysis System (GSAS) for $\text{LaBaCaCu}_3\text{O}_7$ sample reveal that part of La occupies Ba site with a corresponding amount of Ca occupying the nominal RE site. Quantitatively 46% of Ca atoms occupy the usual La site, and the remaining 54% are at the Ba site. It is presumed that a similar situation occurs when Pr is substituted at La site, i.e., part of Pr occupies the Ba site. Unfortunately, the neutron scattering cross sections of Pr and Ba are very similar preventing accurate determination of their occupancies. The oxygen contents of the two samples were found to be 7.01 and 6.86, respectively, for $x=0.0$ and 1.0.

In Fig. 2 are shown the real and imaginary parts of ac susceptibility versus temperature plots for the $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ system with various x values. The inset shows the T_c vs x behavior for the presently studied system and that reported in $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$ system.²¹ The superconducting transition temperature, T_c , is defined as the onset of the diamagnetic transition, which is around 70 K for the unsubstituted sample. T_c decreases with increasing x in both $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ and $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$ systems. In $\text{RE}_{1-x}\text{Pr}_x:123$, the depression of T_c depends strongly on the ionic radius of the host rare earth. Hence a comparison of the $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ system can be made with the Pr substituted La:123 system only. As seen from inset of Fig. 2, the critical Pr concentration (x_{cr}) for destroying superconductivity is 0.70 in the $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ system, while the same is nearly 0.30 for the $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$ system. This shows that Pr is less effective in destroying the superconduc-

FIG. 2. ac susceptibility (both real and imaginary parts) vs temperature plots for $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ system with various x values, the inset shows the T_c vs x behavior for presently studied and reported (Ref. 21) $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$ systems.

tivity of $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ than that of $\text{La}_{1-x}\text{Pr}_x\text{Ba}_2\text{Cu}_3\text{O}_7$.

The susceptibility (χ) of both $x=0.70$ and 1.0 samples showed deviations from the standard Curie-Weiss behavior at 4 and 8 K, respectively. Heat capacity measurements²² also show humps at these temperatures. These results indicate the possibility of magnetic ordering of Pr moments at these temperatures in the two compounds. Incidentally, similar deviation in dc magnetic susceptibility measurements and a broad hump in C_p occurs at 17 K for the $\text{PrBa}_2\text{Cu}_3\text{O}_7$ compound (see, for instance, Ref. 5). Interestingly, while the x_{cr} is higher, the T_N of Pr is lower for the presently studied system than for $\text{La}_{1-x}\text{Pr}_x\text{:123}$. The lower T_N of Pr in the $\text{La}_{1-x}\text{Pr}_x\text{BaCaCu}_3\text{O}_7$ system, perhaps explains the less deleterious effect of the Pr on superconductivity.

The high T_N of Pr in Pr:123 type compounds is presumed to arise from the strong hybridization of Pr 4f orbital with the neighboring Cu-O conduction band.⁵ Decreased oxygen content in Pr:123 compounds, decreases the number of charge carriers in the Cu-O conduction band and increases the Pr to Cu-O distance, which results in a decreased T_N . For example, a T_N of 12 K is reported for $\text{PrBa}_2\text{Cu}_3\text{O}_{6.4}$.²⁷ This shows that the small decrease of oxygen content in our sample of composition $\text{PrBaCaCu}_3\text{O}_{6.86}$ cannot explain solely the lowering of T_N to 8 K. Another possible and more viable reason for the decreased T_N may be the distribution of Pr at both the usual Pr site (sandwiched between two Cu-O planes) and the Ba site. This may result in a lower T_N and a less destructive effect of Pr on superconductivity in the present system.²⁸

In conclusion our study indicates that superconductivity can be induced in $\text{RE}_{1-x}\text{Pr}_x\text{:123}$ compounds for higher x values by separating the Pr from Cu-O conduction band. In this way one can decrease the magnetic interaction of Pr 4f with the Cu-O conduction band and induce superconductivity in Pr:123 type compounds.

Magnetic properties of $\text{Pb}_2\text{Sr}_2\text{PrCu}_3\text{O}_8$ studied by ac susceptibility

S. Y. Wu, Y. C. Chang, K. C. Lee, and W.-H. Li

Department of Physics, National Central University, Chung-Li, Taiwan 32054, Republic of China

The magnetic responses of vacuum annealed polycrystalline $\text{Pb}_2\text{Sr}_2\text{PrCu}_3\text{O}_8$ to a magnetic field have been studied by ac magnetic susceptibility measurements, where both the in-phase component χ' and the out-of-phase component χ'' were measured. Diamagnetic responses in $\chi'(T)$ below 60 K were clearly seen, showing the occurrence of superconductivity, but it is filamentary. This filamentary superconductivity was also evident in the $\chi''(T)$. Under an applied dc field, both the $\chi'(T)$ and $\chi''(T)$ behave as what are expected for a superconducting system. At lower temperatures, a well-defined peak associated with the Pr spin ordering is also clearly revealed at 5 K. Correspondingly, an anomaly is also seen in the specific heat data. © 1998 American Institute of Physics. [S0021-8979(98)22911-2]

Since the discovery of high- T_c oxides, intensive studies have been made on this class of material, especially on their superconducting and magnetic properties. Yet, many physical phenomena are still not well understood. In the Pb-based 2213 systems, $\text{Pb}_2\text{Sr}_2\text{RCu}_3\text{O}_{8+x}$ (R=rare earth), superconductivity around 70 K has been observed in the alkaline earth metal doped compounds.^{1,2} For the alkaline earth metal free compounds, filamentary superconductivity and superconducting-like resistivity drop around 70 K have been reported.^{3,4} The crystal structure of the $\text{Pb}_2\text{Sr}_2\text{RCu}_3\text{O}_{8+x}$ compound can be obtained from the well-known $\text{RBa}_2\text{Cu}_3\text{O}_{6+x}$ structure by replacing the CuO-chain layer in the latter with two PbO and one Cu layers for the former. In this paper, we report the observations of superconductivity and magnetic order of the Pr spins in a polycrystalline $\text{Pb}_2\text{Sr}_2\text{PrCu}_3\text{O}_8$ compound by using ac magnetic susceptibility and specific heat measurements.

A vacuum annealed polycrystalline sample of $\text{Pb}_2\text{Sr}_2\text{PrCu}_3\text{O}_8$ was prepared by the two-stage solid state reaction techniques. High purity powders of SrCO_3 , Pr_2O_3 , and CuO with a ratio of Sr:Pr:Cu=2:1:3 were well mixed and calcined at 930 °C in air for 12 h with two intermediate grinding. The obtained precursor $\text{Sr}_2\text{PrCu}_3\text{O}_x$ powders was then mixed with an appropriate amount of high purity PbO powder, followed by a heating in air at 750 °C for 12 h with three intermediate grinding. The reacted powders were then pressed into pellets and annealed at 870 °C in vacuum of pressure 10^{-2} Torr for 24 h, followed by furnace cooling to room temperature. The sample fabricated was characterized by a complete structural analysis using x-ray diffraction and Rietveld analysis.⁵ High resolution diffraction pattern taken at room temperature was analyzed using the General Structure Analysis System (GSAS) program of Larson and von Dreele.⁶ The diffraction pattern obtained may be well described using the structure reported⁷ for $\text{Pb}_2\text{Sr}_2\text{YCu}_3\text{O}_8$. The refinement was carried out assuming the symmetry of space group $P2_1/m$. In the refining process, all structural parameters were allowed to vary simultaneously unit R_w , the weighted R factor,⁶ differed by less than one part in a thousand in two successive cycles. Only a few additional very weak peaks were present, showing the compound is practi-

cally of single phase. We estimated that the impurity phases should be less than 3%. Careful analysis of the occupancy factor of the oxygen atoms showed that the O sites were almost fully occupied. The compound crystallizes into a monoclinic phase with lattice constants $a=5.3901(4)\text{Å}$, $b=5.4302(4)\text{Å}$, $c=15.655(1)\text{Å}$, and the angle between the a and b axes $\beta=89.69(4)^\circ$ at room temperature.

The ac susceptibility measurements were performed using a Lake Shore 7221 ac susceptometer, with which both the in-phase component χ' and the out-of-phase component χ'' can be measured simultaneously. Shown in Fig. 1 are the low temperature portions of $\chi'(T)$ measured using driving fields of rms strength 1 Oe and at three frequencies. Above 60 K, $\chi'(T)$ is essentially independent of the driving frequency used, and it follows the Curie—Weiss law. The solid curve shown in Fig. 1 is an extrapolation of a fit to $\chi'(T)$ data obtained between 80 and 320 K (not shown) to the expression $\chi'_0 + C/(T - \theta)$, where χ'_0 is a temperature independent constant represents the contribution from the conduction electrons. Using the fitted value for the Curie—Weiss constant C , we obtained a value of $2.90\mu_B$ for the effective moment. The value obtained for μ_{eff} is about 20% smaller

FIG. 1. Temperature dependence of χ' measured at three driving frequencies. Diamagnetic responses below 60 K and a well-defined peak at 5 K are clearly seen.

FIG. 2. Temperature dependence of the specific heat measured using the time constant techniques (Ref. 8). The anomaly seen at low temperatures is associated with the ordering of the Pr spins. The solid curve shown is a fit of the data obtained between 15 K $\leq T \leq$ 40 K (not shown) to the expression $C/T = \gamma + \beta T^2$, with $\gamma = 212$ mJ/mol K² for the contribution from electrons and $\beta = 6.4$ mJ/mol K⁴ from phonons.

than the value of $3.58 \mu_B$ expected for the free Pr ions. This discrepancy likely originates from the crystalline electric field effects.

The main features seen in Fig. 1 are the diamagnetic responses occur below ~ 60 K and the well-defined peak at 5 K. The diamagnetic responses, which are essentially independent of the driving frequency used, signifies the occurrence of superconductivity. Although negative values for χ' were obtained at temperatures below 40 K, it is obvious that the screening effect is never complete. By fitting the $\chi'(T)$ data obtained between 20 and 60 K to the Meissner diamagnetic screening function, it shows that only about 2% of the sample volume shows a superconducting phase. The superconductivity observed is only filamentary. It is possible that the observed superconductivity is of impurity-origin, since a 2% impurity volume can usually not be identified by x-ray diffraction technique. The other possible explanation, however, is that oxygen is unevenly distributed in the sample, that is likely to happen for high- T_c oxides, and superconductivity occurs only in the portion that contains "correct" oxygen concentration.

At lower temperatures, χ' begins to show an upturn around 15 K. A peak in $\chi'(T)$ is clearly seen at 5 K. Correspondingly, an anomaly is also seen in the specific heat data shown in Fig. 2, where the low temperature portion of C/T vs T^2 is plotted. Both anomalies are associated with the ordering of the Pr spins, and it has an antiferromagnetic character as a cusp is present in $\chi'(T)$. The correlated Pr spins respond "better" to lower driving frequencies, as the peak in $\chi'(T)$ goes higher when lower frequencies were used. This frequency-dependent behavior becomes less pronounced in the higher frequency regime. Beyond 5000 Hz, $\chi'(T)$ becomes essentially frequency independent. It, nevertheless, still indicates that the relaxation rate of the correlated Pr spins is relatively slow. We note that no frequency dependence was found for the paramagnetic Pr spins. Showing their relaxation rate is far beyond the driving frequency used.

In Fig. 3(a) we show the effects of the strength of the driving field on $\chi'(T)$. As the strength of the driving field

FIG. 3. Effects of the strength of driving field on (a) $\chi'(T)$ and (b) $\chi''(T)$.

was raised, the diamagnetic responses become weaker while it places no obvious effects on the paramagnetic and spin ordered states. These behaviors are understandable, since superconductivity is expected to be weakened by a magnetic field and a field of strength several Oe is not strong enough to alter Pr spins. The Pr ordering and the occurrence of superconductivity are also evident in $\chi''(T)$ shown in Fig. 3(b), where two dissipation peaks at 5 and 18 K are clearly seen. The former is associated with the losses occurring as the Pr spins order, and the latter shows the losses to the superconducting grains. The temperature at which $\chi'(T)$ reaches its minimum value matches to the temperature at which $\chi''(T)$ peaks. This phenomenon may be understood easier if we first consider a superconducting system to be at a low temperature, at which the flux is fully excluded from the polycrystalline grains. The contribution to χ'' is then small. As the field begins to penetrate into the grains at a higher temperature, the loss increases. It peaks when the field penetrates into the grains completely. Above this temperature, less and less of the grain volume remains superconducting, and the diamagnetic response become weaker while the loss relaxed.

The effects of an applied dc magnetic field on the magnetic responses at two representative temperatures are shown in Fig. 4. At 20 K, the main contribution to χ' is from the intragranular screening current, the diamagnetic response was found to be weakened by the applied dc field, as expected. Figure 4(a) shows that the diamagnetic response is mostly suppressed by an applied field of strength 2 kOe, beyond that it is gradually smeared, and is still evident at 10 kOe. At 4.5 K, χ' first increasing and then decreasing with increasing strength of the applied field, as seen in Fig. 4(b). Neutron diffraction measurements⁹ have confirmed that the Pr spin

FIG. 4. Effects of an applied dc magnetic field on χ' at two representative temperatures.

ordering is antiferromagnetic in nature. An applied field is expected to reduce the magnetic response from ordered Pr spins. The enhancing of χ' by a low applied field than originates from the suppression of the diamagnetic response, that

indicates the superconductivity remains as the Pr spins order. Beyond 2 kOe, this suppression effect is much reduced, as seen in Fig. 4(a), the contribution to χ' from ordered Pr spins becomes dominating and a decreasing χ' with increasing strength of the applied field is then observed.

In summary, we have observed filamentary superconductivity and Pr spin ordering in a vacuum annealed polycrystalline $\text{Pb}_2\text{Sr}_2\text{PrCu}_3\text{O}_8$ using ac susceptibility and specific heat measurements. Competition between superconductivity and magnetic order was seen as an applied magnetic field is present. An applied field of strength 2 kOe suppresses about 80% of the diamagnetic response, it, however, is still evident at a strength of 10 kOe.

Specific heat, magnetization and C-isotope effect of $\text{Y}_2\text{C}_2(\text{Br},\text{I})_2$ superconductors

W. Schnelle, R. W. Henn, Th. Gulden, R. K. Kremer, and A. Simon

Max-Planck-Institut für Festkörperforschung, Heisenbergstraße 1, 70569 Stuttgart, Germany

The specific heat $c_p(T)$ and the magnetization $M(B,T)$ of the layered superconductors $\text{Y}_2\text{C}_2\text{I}_2$, $\text{Y}_2^{13}\text{C}_2\text{I}_2$ ($T_c \approx 10$ K), $\text{Y}_2\text{C}_2\text{Br}_2$ ($T_c \approx 5$ K), and of $\text{Y}_2\text{C}_2\text{Br}_{0.5}\text{I}_{1.5}$ ($T_c \approx 11.6$ K) were measured from 2–80 K in magnetic fields up to 10 T. All samples exhibit sharp phase transitions in zero field. The jump Δc_p at T_c is drastically reduced in amplitude and broadens significantly with increasing field. The temperature dependence of $\Delta c_p(T)$ and of $B_c(T)$ is analyzed and is consistent with strong electron–phonon coupling. The $^{13}\text{C}/^{12}\text{C}$ isotope effect of $\text{Y}_2\text{C}_2\text{X}_2$ is found to be nearly zero. In contrast to this finding the 3-dimensional parent compound YC_2 shows weak-coupling BCS behavior. The anisotropic thermodynamic parameters of the materials are evaluated and discussed.

I. INTRODUCTION

Materials with layered crystal structure display a wealth of unusual electronic effects. Well known recent examples are the exceptionally high transition temperatures of the cuprate high T_c superconductors and the manganates. In the Bi, Tl, and Hg based cuprate systems the anisotropic superconducting parameters are strongly modified by the thickness and character of the rocksalt-type building blocks between the Cu–O units which essentially contain the carriers of the superconductivity.¹ In addition the Bi, Tl, or Hg–O units provide a charge reservoir for the doping of the Cu–O layers. However, other superconducting materials with quasi-two-dimensional layered structure were studied intensively since the 1970s. Among them are the layered Ta and Nb dichalcogenides and their intercalated derivatives² and intercalated graphites which display less spectacular transition temperatures. In these materials the interlayer distance can be varied by intercalation and the transition from three-dimensional to quasi-two-dimensional superconductivity could be studied favorably. The variation of the interlayer coupling has a tremendous effect on the superconducting properties, e.g., T_c and the critical fields. It is widely believed that low-dimensional and especially layered structures provide optimum conditions for superconductivity with high T_c .^{3,4}

In this contribution we report on thermodynamic measurements on superconducting metal-rich rare-earth carbide halides $\text{RE}_2\text{C}_2\text{X}_2$ with RE either Y or La, and the halide X being Cl, Br, or I. These compounds were found to be superconducting^{5,6} with a maximum T_c up to 11.6 K. They adopt a layered crystal structure (monoclinic $\text{Gd}_2\text{C}_2\text{Cl}_2$ type, space group $\text{C2/m}^{7,8}$) with units of bilayers of close-packed RE metal atoms which are sandwiched between layers of halogen atoms X (see Fig. 1). The thick and strongly electronegative halogen atom double layers lead to ionic bonds between X and RE atoms and to a van der Waals gap resulting in very weak bonds between adjacent RE_2C_2 building blocks (distance 6.85 Å in $\text{Y}_2\text{C}_2\text{Br}_2$). In the RE atom bilayers (Y–Y distance 3.76 Å) the octahedral voids are filled with dimeric C–C dumbbells. Depending on the mean radius of the halogen composition $\text{X}=(\text{Cl},\text{Br},\text{I})$ the stacking se-

quence of the layers, the lattice constants, and the T_c varies.⁶ T_c reaches a maximum of 11.6 K at a composition of $\text{Y}_2\text{C}_2\text{Br}_{0.5}\text{I}_{1.5}$.^{6,9} The layered compounds $\text{Y}_2\text{C}_2\text{X}_2$ are closely related to the three-dimensional superconducting dicarbide YC_2 .¹⁰ This compound is a textbook example for a weak coupling BCS superconductor with $\kappa_{\text{GL}} \approx 1/\sqrt{2}$ and with a clear $^{13}\text{C}/^{12}\text{C}$ isotope effect of $-0.51(7)$ demonstrating that the vibrations of the C–C dumbbells are important for the pairing mechanism.⁹

II. RESULTS AND DISCUSSION

The samples were prepared by heating Y metal chips, YX_3 , and graphite powder to 1320 K in sealed tantalum crucibles.⁷ The <50 μm sized crystallites were single phase as characterized by x-ray and neutron diffraction.⁹ The compounds are very sensitive to moisture. All handling and measurements were done in a glove box with dried argon atmosphere or in specially fabricated quartz or Duran glass ampoules. For cryogenic measurements the ampoules were filled with He exchange gas. Specific heat was measured

FIG. 1. Perspective view of the crystal structure of $3s\text{-Y}_2\text{C}_2\text{Br}_2$ along [010]. The monoclinic unit cell is indicated by the dashed line.

FIG. 2. Low field part of the isothermal magnetic polarization of $\text{Y}_2\text{C}_2\text{I}_2$ for $2.0 \text{ K} < T < 9.9 \text{ K}$.

with the quasiadiabatic step-heating method in an improved version of a calorimeter as described in Ref. 11. Magnetic fields up to 10 T were applied. The shift of the Cernox thermometer temperature calibration curve with field $\Delta T(R, B)$ was calibrated *in-situ* and corrected for in the $c_p(T)$ measurements.

Isothermal dc-magnetization measurements of the $\text{Y}_2\text{C}_2\text{I}_2$ sample (Fig. 2) were recorded in a SQUID-magnetometer. The curves are typical for a type-II superconductor with a large Ginzburg-Landau (GL) parameter ($\kappa_{\text{GL}} \approx 60$). An upper estimate for the first critical field $B_{c1}(0) = 6 \text{ mT}$ is gained from the deviation of the isotherms from their initial linear rise. The interceptions of the isotherms with $B = 0$ were used for the determination of the upper critical field $B_{c2}(0) = 11.8(2) \text{ T}$. The corresponding values for $\text{Y}_2\text{C}_2\text{Br}_2$ are $B_{c1} < 1.5 \text{ mT}$, $B_{c2} = 3.0(2) \text{ T}$, and $\kappa_{\text{GL}} \approx 50$.⁹

The temperature dependence of the critical fields and of the electronic specific heat $\Delta c_p(T)$ of a superconductor is given by its gap, i.e., determined by the electron-phonon coupling strength $\alpha = \Delta(0)/k_B T_c$. A phenomenological model describing the thermodynamics at arbitrary coupling strength is given by the α -model by Padamsee *et al.*¹² This model is fitted to the data of the thermodynamic critical field $B_{\text{cth}}(T)$ obtained by integration of the isotherms. The result for $\text{Y}_2\text{C}_2\text{I}_2$ is $\alpha = 2.15 \pm 0.10$ which is in the range of intermediate strong coupling. The deviation of $B_{\text{cth}}(T)$ from the parabolic law is quite small and therefore the thermodynamics of $\text{Y}_2\text{C}_2\text{I}_2$ is described well by the two fluid (2fl) model.

The specific heat of the four $\text{Y}_2\text{C}_2\text{X}_2$ compounds is plotted in Fig. 3. As expected the bromine compound has the lowest lattice specific heat, i.e., the highest Debye temperature ($\Theta_D(0) \propto 1/\sqrt{M}$; M = molar mass). We roughly estimate $\theta_D = 240 \pm 10 \text{ K}$ for the $\text{Y}_2\text{C}_2\text{Br}_2$ and $210 \pm 10 \text{ K}$ for $\text{Y}_2\text{C}_2\text{I}_2$, taking into consideration the $\gamma_{2\text{fl}}$ -values as determined below.

Powder samples sealed in Duran glass ampoules with ^4He contact gas ($\approx 1 \text{ bar}$) is a technique utilized successfully in c_p measurements for many years in our laboratory. However, in measurements on $\text{Y}_2\text{C}_2\text{X}_2$ samples we detected an

FIG. 3. Specific heat $c_p(T)/T$ of $\text{Y}_2\text{C}_2\text{X}_2$ samples. The data for $\text{Y}_2^{13}\text{C}_2\text{I}_2$ and $\text{Y}_2\text{C}_2\text{I}_2$ are identical within error bars.

upturn in c_p/T at temperatures below 4.4 K ¹³ and broad peaks at ≈ 3.7 and $\approx 2.0 \text{ K}$. These peaks we assign to the desorption and to the λ transition of ^4He adsorbed on the (large) internal surface of the layered $\text{Y}_2\text{C}_2\text{X}_2$ crystallites. ^3He offers the advantage of a substantially higher vapor pressure below 5 K . We therefore resealed the $\text{Y}_2\text{C}_2\text{X}_2$ samples under $\approx 0.5 \text{ bar}$ of ^3He gas at ambient temperature.

In Fig. 4 the specific heat of $\text{Y}_2\text{C}_2\text{I}_2$ (sample from Ref. 13 with ^3He contact gas) is given in a c_p/T vs T^2 representation for various magnetic fields. The results above 6 K are identical to the previous data¹³ and there are no peaks below 4.2 K . However, even with this precautions an upturn in c_p/T below 3.2 K remains. This may originate from ^3He desorption and/or $\approx 0.5\%$ of $S = \frac{1}{2}$ paramagnetic impurities found by high field susceptibility measurements.^{9,13} A clear phase transition, a sharp step in $c_p(T)$, can be seen at 9.94 K (calorimetric midpoint) for $B = 0 \text{ T}$, indicating bulk superconductivity.¹³ Closer inspection of the data in 6 and 10 T shows that the step at $T_c(B)$ is depressed to temperatures below 4 K for a field of 10 T . The 10 T data extrapolate to an intercept $\gamma^* \approx 35(5) \text{ mJ/mol K}^2$.

The midpoint of the transition of the iodine sample with ^{13}C is at 9.76 K which would correspond to an $^{13}\text{C}/^{12}\text{C}$ isotope effect of -0.23 . However, the T_c of our samples of

FIG. 4. Specific heat $c_p(T, B)/T$ vs T^2 of the $\text{Y}_2\text{C}_2\text{I}_2$ sample in magnetic fields up to 10 T .

FIG. 5. Difference $\Delta c_p(T, B)/T = [c_p(T, B) - c_p(T, 10 \text{ T})]/T$ of the specific heat of the $\text{Y}_2\text{C}_2\text{I}_2$ sample. The full line is a fit with the two fluid model, the dashed line a fit with the weak coupling BCS theory (see the text).

$\text{Y}_2\text{C}_2\text{I}_2$ show some scatter and the result should be taken more as an upper limit for this isotope effect. In an earlier determination of the $^{13}\text{C}/^{12}\text{C}$ isotope effect of the bromine compound, which has a very good reproducibility of T_c , we found 0.00 ± 0.05 by susceptibility measurements.^{6,9}

Figure 5 displays the difference $\Delta c_p(T, B)$ between $c_p(T, B)$ and $c_p(T, 10 \text{ T})$, i.e., the purely electronic specific heat difference between superconducting and normal state. In this representation it can be clearly seen that the superconducting transition in magnetic fields broadens strongly and two characteristic temperatures becomes discernable. For example, in the curve for $B = 0.5 \text{ T}$ a clear kink at 7.74 K and a first deviation from the expected straight step at 9.45 K are visible. The sample consists of small crystallites with c axes enclosing a random angle ϕ to the direction of the magnetic field B . This results in a distribution of the critical field $B_c(T, \phi)$ limited by the values for $B \parallel c$ and $B \perp c$. The lower temperature kinks in the $\Delta c_p(T, B)$ curves have therefore to be assigned to $T_c(B)$ with B perpendicular to the layers and the higher characteristic temperature to $T_c(B)$ for B parallel to the layer structure, i.e., B perpendicular to the c axis. An evaluation of the temperatures of the kinks and of the first

deviation from the idealized steps for all measured fields yields $B_{c2\parallel}(0) \geq 7 \text{ T}$ ($B \perp c$) and $B_{c2\perp}(0) \geq 1.5 \text{ T}$. The anisotropy factor is about $4.7(3)$, consistent with values of ≈ 5 from determinations on larger single crystals of $\text{Y}_2\text{C}_2\text{I}_2$ with magnetization measurements.⁹ This value is similar to that of fully oxygenated $\text{YBa}_2\text{Cu}_3\text{O}_7$.¹

An analysis of the electronic specific heat difference $\Delta c_p(T, 0)$ of $\text{Y}_2\text{C}_2\text{I}_2$ between 0 and 10 T was carried out within the weak coupling BCS theory¹⁴ (Fig. 5 dashed line) and the two fluid (2fl) model (Fig. 5 full line). The excellent agreement of the data with the latter model is also rendered from the interception of the $c_p(T)$ curves in 0 and 10 T at $0.58T_c$ in agreement with the 2fl model result. The fitted parameters are the electronic coefficient $\gamma_{2fl} = 9.01(6) \text{ mJ/mol K}^2$ and $T_c = 9.94(1) \text{ K}$. These values are very near to those determined in Ref. 13. The narrow transition width of about $0.01 T_c$ proves the sample's homogeneity.

In conclusion, the layered $\text{Y}_2\text{C}_2\text{X}_2$ compounds are intermediate strong coupling, extreme type-II bulk superconductors with T_c upto 11.6 K at present. These findings differ markedly from that for the structurally closely related carbide YC_2 which has a three-dimensional structure.^{13,10}

We have studied magnetothermal instabilities both theoretically and experimentally. Magnetostriction and magnetization hysteresis loops with flux jumps were calculated over a wide range of experimental parameters employing three critical state models: the original Bean model, the Kim-Anderson model, and the exponential model. The influence of the magnetic prehistory on the flux jumps, magnetostriction, and the magnetization was investigated for the LaSrCuO crystal. *H*-*T* diagrams of flux instabilities were constructed from calculation and from experimental results. One can see good qualitative agreement between these two diagrams. © 1998 American Institute of Physics. [S0021-8979(98)30111-5]

I. INTRODUCTION

When the magnetic field is ramping, the appearance of a small increase temperature leads to decrease of the value of the critical current density of hard type II superconductors. In adiabatic conditions this increases dissipation and can lead to a "thermomagnetic catastrophe." As a result, giant flux jumps appear and the sample goes to the resistive or normal state. The investigation of flux instabilities in high temperature superconductors (HTSCs) is interesting because of their potential applications as well as the importance of gaining a fundamental understanding of the phenomenon. We have studied magnetothermal instabilities both theoretically and experimentally in LaSrCuO.

II. *H*-*T* DIAGRAM OF FLUX INSTABILITIES: THEORY AND EXPERIMENT

The influence of the magnetic prehistory on the flux jumps was investigated in the LaSrCuO crystal. Magnetostriction and magnetization hysteresis loops with flux jumps were calculated employing three critical state models: the original Bean model, the Kim-Anderson model, and the exponential model.

A. Critical state

Let us consider the pinning induced magnetization and magnetostriction loops with flux jumps for a specimen having a slab geometry with thickness of $L = 2d$ ($-d \leq x \leq d$). Suppose that the external magnetic field H_e is applied parallel to the slab face. The magnetic field profile $H(x)$ inside the slab is given by the solutions of the critical state equation,

$$dB/dx = -\mu_0 J(x), \quad (1)$$

where current density $|J(x)| \leq |J_c(x)|\mu_0$, the permeability of vacuum. This critical-state equation can be used to determine

the magnetization and the magnetostriction when $H \gg H_{c1}$ (for YBCO the lower critical field H is of the order of several hundred gauss at $T=0$ while the flux jumps are observed at the fields $\mu_0 H$ of the order of several tesla). According to the Kim-Anderson model¹

$$J_c(B) = \pm J_0(T) B_0 / (B_0 + |B|); \quad (2)$$

here B_0 is a phenomenological parameter and J_0 is the critical current density at zero magnetic field B in HTS materials $J_0(T) \approx J_0(0)(1 - T/T_c)$. Integration of Eqs. (1) and (2) gives

$$B_{\pm}(x) = B_0 - [(B_0 - B^*)^2 \pm 2\mu_0 J_0(x - x^*) B_0]^{1/2}, \quad (3)$$

$$B(x) < 0,$$

$$B_{\pm}(x) = -B_0 + [(B_0 + B^*)^2 \pm 2\mu_0 J_0(x - x^*) B_0]^{1/2},$$

$$B(x) > 0.$$

The sign $+$ ($-$) corresponds to domains of vortices where $dB/dx > 0$ ($dB/dx < 0$) and the field $B^* = B(x^*)$. In the exponential model² the critical current density is expressed as follows:

$$J_c(B) = \pm J_0 \exp(-B/B_0), \quad (4)$$

and the sign shows the flow direction of the current. Integration of Eqs. (1) and (4) provides the local field distribution,

$$B_{\pm}(x) = B_0 \ln[\exp(B^*/B_0) \pm \mu_0 J_0(x - x^*)/B_0],$$

$$B(x) > 0,$$

$$B_{\pm}(x) = B_0 \ln[\exp(-B^*/B_0) \pm \mu_0 J_0(x - x^*)/B_0],$$

$$B(x) < 0. \quad (5)$$

Here the sign $+$ ($-$) again corresponds to the local field distribution where $dB/dx > 0$ (or $dB/dx < 0$) and the boundary field $B^* = B(x^*)$. The full magnetic field profile in the sample is given by a combination of solutions (3) and (5). The parameters x^* and B^* are chosen so that the condition $\mu_0 H_e = B(x=0)$ holds and the field $B(x)$ distribution is con-

^{a)}Electronic mail: chaban@host.dipt.donetsk.ua

tinuous. Comparison of solutions (3) and (5) shows that they are close to each other if $B^*/B_0 \ll 1$. From the four solutions [those in (3) and (5)], all the necessary magnetic field profiles can be constructed.^{3,4} When the value of the magnetic field $B(x)$ is known, the magnetization M and magnetostriction $\Delta L/L_0$ can be calculated by simple integration

$$\Delta L(B)/L_0 = -1/(\mu_0 E L_0) \int_0^d [B_e^2 - B^2(x)] dx, \quad (6)$$

$$M(B) = 1/(\mu_0 d) \int_0^d B(x) dx - H_e; \quad (7)$$

here E is the elastic constant of the material along the x axis, $L = 2d$.

B. Flux jumps, instability criterion, magnetization, and magnetostriction loops

The instability criterion (under adiabatic conditions) in the case of the Kim–Anderson type critical current density $J_c(B)$ can be derived analytically.³ For the exponential model (4) it is not possible and we have used in this case the calculations based on the adiabatic flux- B jump instability criterion. Let the applied field H_e increases (decreases) by a small amount ΔH_e ($|\Delta H_e| \ll |H_e|$). Due to the moving of flux lines, the magnetic field, $B(x)$, in the sample, increases by $\Delta B(x)$. The $\Delta B(x)$ value has to be calculated from Eq. (1) in the following way. Let x_i be the points at which the $B(x_i) = B_i$ values are calculated with the index $1 \leq i \leq n$, $x_1 = 0$, $x_n = d$ and $B^0(x)$ as the initial local field. We put $\Delta B = B_{i+1}^0 - B_i$, where $i > 1$, $B_i = B(x=0) = \mu_0 H_e$. The critical state Eq. (1) gives the conditions one

$$B(x_{i+1}) = \begin{cases} B(x_i) + \Delta B & |\Delta B| < \mu_0 J_c(B_i) \\ B(x_i) + \text{sign}(\Delta B) \mu_0 J_c(B_i) dx, & |\Delta B| > \mu_0 J_c(B_i) \end{cases} \quad (8)$$

where $dx = x_{i+1} - x_i$.

Due to exchange of the magnetic field, $B(x)$, the energy per unit volume, Q , is dissipated in the vicinity of x where

$$Q(x) = J_c(x) \int_x^d [B(x') - B^0(x')] dx'. \quad (9)$$

Under local adiabatic conditions one obtains

$$\Delta T(x) = Q(x)/C_V, \quad (10)$$

where C_V is the specific heat of the superconductor. For YBCO,⁵ C_V (1–26 K) (J cm^{-3}) = $2.68 \times 10^{-4} T^{-2} + 1.01 \times 10^{-4} T + 2.53 \times 10^{-6} T^3 + 7.17 \times 10^{-9} T^5$ and C_V (26–100 K) (J cm^{-3}) = $2.02 \times 10^{-4} T^2 - 7.82 \times 10^{-9} T^4$. The rise of temperature ΔT reduces the critical current J_c ,

$$\Delta J_c(x) = \partial J_c / \partial T \Delta T(x). \quad (11)$$

According to the critical state Eqs. (8), the reduction in J_c leads to a decrease in the shielding ability of the superconductor by ΔH_s , where

$$\Delta H_s = - \int_x^d \Delta J_c(x') dx'. \quad (12)$$

The magnetic configuration is unstable with respect to a flux jump if $\Delta H_s > \Delta H_e$.^{6,7}

During a flux jump, the temperature inside the sample increases and reaches a maximum value $T^* < T_c$, which is assumed to be independent of the position x inside the sample. The critical current density at T^* is $J_c(T^*) < J_c(T_0)$, where T_0 is the temperature of the sample before the flux jump. Therefore, according to the critical state conditions, the magnetic field configuration is given by the solution of Eqs. (8) for $J_c = J_c(T^*)$. After the flux jump the temperature inside the sample returns to the starting value T_0 , but the magnetic field profiles in the slab are unchanged, i.e., they are the same as for $T = T^*$. An increase (decrease) of the external field, H_e , leads to the new magnetic field distributions. It is assumed that the maximum temperature, T^* , reached during a jump, which is less than T_c , is the same for all jumps. Generally speaking the T^* value is unknown because it depends on the microstructure of the sample, the sweep rate, and the adiabatic conditions of the sample. The critical state conditions (8) for a type II superconductor allow one to calculate magnetic field profiles in a slab and for any number of the flux jumps independent of the magnetic prehistory.

These results and experimental data^{3,4} are used for computer simulations. Magnetostriction and magnetization loops are constructed over a wide range of experimental parameters. In Fig. 1, one can see an example of theoretically calculated magnetostriction and magnetization hysteresis loops with magnetostriction and magnetization jumps on the basis of the Kim–Anderson model. ΔH_{rj} is the flux instability range of the magnetic field. Similar calculations were per-

FIG. 1. Magnetization and magnetostriction loops with flux jumps, calculated by the Kim–Anderson model.

FIG. 2. H - T ranges of the flux instability from (a) experiment on the LaSrCuO and from (b) calculation, $d=5$ mm, $j_c=10^9$ A/m², $B_0=2$ T, B_p full penetration field, and (c) experiment on the Nb from (Ref. 8).

formed for different temperatures and were used for the construction of the H - T phase diagram of flux instability [Fig. 2(b)].

The experiments reported here have been performed on a La_{1.85}Sr_{0.15}CuO₄ single crystal with its fields oriented along the c axis. The sample had dimensions of $2.15 \times 2.24 \times 5.42$ mm³, with the c axis the shortest test axis. The change of length ΔL of the sample was measured in the ab plane along the longest dimension using a strain gauge technique. The resistance change of strain gauges is measured by an ac bridge. The magnetic field was swept at a constant cyclic rate of 0.5 T/min after the sample was zero-field cooled to the measuring temperature. An onset temperature of superconductivity of 35.5 K was observed in a field of 10 G. Figure 3 shows evidence of flux jump instabilities in the virgin magnetization curve for the LaSrCuO single crystal. H_{irr} is the field where M becomes irreversible.

As can be seen from Figs. 2(a) and 2(c) the overall picture of the H - T ranges of flux instability are similar in shape for Nb (Ref. 8) and LaSrCuO. One can also see good qualitative agreement between the experimental and the calculated phase diagrams. That is to say, the Kim-Anderson

FIG. 3. Magnetostriction loops for different temperatures of LaSrCuO.

model is applicable at large distances from the irreversibility line for HTSC materials whereas the exponential model is applicable in the vicinity of the irreversibility line.

As is clear from both calculation and experiment, the first and third quadrants have significantly fewer flux jumps than the second and fourth quadrants. For example, for the $T=4$ K curve [Fig. 1(a)] and experiment,⁹ flux jumps are completely absent in the first and third quadrants. According to our calculation, the difference in the frequency of occurrence of the flux jumps in the different quadrants is related to the shape of the flux profiles in the various quadrants.

Magnetic memory effect in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}/(\text{BiDy})_3(\text{FeGa})_5\text{O}_{12}$ heterostructures

D. Mou, A. M. Grishin,^{a)} and K. V. Rao^{b)}

Department of Condensed Matter Physics, Royal Institute of Technology, S-100 44 Stockholm, Sweden

$\text{YBa}_2\text{Cu}_3\text{O}_{7-x}/(\text{YBCO})(\text{BiDy})_3(\text{FeGa})_5\text{O}_{12}$ heterostructures have been prepared on ceramic glass substrates by Nd-yttrium–aluminum–garnet pulsed laser ablation. Both YBCO and BiDy-IG garnet layers are found to be polycrystalline without any preferential crystallite orientation. Magnetic hysteresis loop measurements made before and after YBCO deposition reveal perpendicular magnetic anisotropy in the garnet film. The resistance versus temperature measurements indicate that the YBCO layer contains both superconducting and semiconducting phases and exhibits a broad superconducting transition with $T_{C|R=0} = 22$ K. The resistivity of the fabricated heterostructures was found to be very sensitive to external magnetic field and the remnant magnetization of the garnet layer. At 18 K, in a magnetic field of 0.5 T applied perpendicular to the surface of the sample, the magnetoresistance figure of merit $\Delta R/\Delta H$ reaches the value of $0.26 \text{ } \Omega/\text{Oe}$ and the absolute resistance value of the YBCO channel changes from the m Ω range up to k Ω . In the wide fluctuation temperature range (from 22 to 80 K), the $R(T)$ curve of the YBCO layer is strongly modulated by the remnant magnetization of the garnet layer, clearly exhibiting a magnetic memory effect. A reduction of as much as 9 K in $T_{C|R=0}$ is observed when the garnet layer has remnant magnetization after having been magnetized. At a measuring current of 1 A/cm^2 , the output voltage obtainable is in the mV range, which is adequate for use in nonvolatile memory applications. © 1998 American Institute of Physics. I. INTRODUCTION

The discovery of high- T_c oxide superconductors stimulated widely study of their electronic applications. Many studies on high- T_c superconducting electric field effect transistors (SuFET)^{1–5} and high- T_c superconducting flux flow transistors (SFFT)^{6,7} have been carried out. However, high- T_c superconductor (HTSC)/magnetic layer-type heterostructures for memory device applications have not yet been discussed. Also, most of the basic studies, as well as proposed applications, have been focused on superconducting state of the high- T_c oxides. Only recently, the properties of semiconducting $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ (YBCO) films are being investigated and the potential application as bolometer has been proposed.^{8–10} The performance of such bolometers and SFTTs can be achieved at levels as high as the temperature sensitivity of the resistivity of YBCO thin film containing superconducting and semiconducting mixed phases and the corresponding magnetic field.

Another area of great potential for nanoelectronics is *in situ* pulsed laser deposited complex oxide heterostructures, with *competing interactions* (ferroelectric, magnetic, and HTSC), which is as yet rarely explored. In this study, we have investigated the magnetic field and magnetic memory effects in pulsed laser deposited YBCO/BiDy-IG heterostructures containing superconducting and semiconducting mixed phases to the corresponding oxygen nonstoichiometric YBCO.

II. EXPERIMENTAL RESULTS AND DISCUSSIONS

A Nd-yttrium–aluminum–garnet (YAG) pulsed laser ablation system was used to fabricate the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ (YBCO) and $(\text{BiDy})_3(\text{FeGa})_5\text{O}_{12}$ (BiDy-IG) thin film heterostructures on commercial ceramic glass substrates. The wavelength, repetition frequency, and the pulsed width of the laser were 355 nm, 10 Hz, and 10 ns, respectively. The focused laser beam with energy density of 3 to 4 J/cm² was directed on the rotating ceramic YBCO or BiDy-IG target with the incident angle of 45° in order to make the laser plume perpendicular to the substrate surface (on-axis deposition). The distance between the targets and the substrates was 55 mm. The vacuum chamber was evacuated to base pressure $<10^{-5}$ Torr before introducing pure oxygen gas. The BiDy-IG films were deposited at room temperature with the oxygen pressure of 40 mTorr and then postannealed in the range of 650–760 °C for 2 to 3 min. X-ray diffraction (XRD) indicated the BiDy-IG films were polycrystalline without a preferred orientation of the crystallites.

After depositing the BiDy-IG layer the YBCO layer is deposited, at 760 °C in a oxygen pressure of 200 mTorr, on the garnet covered ceramic glass substrates, and then the heterostructure is cooled down to 450 °C to anneal it in oxygen pressure of 600 Torr for one hour. XRD patterns indicated that both YBCO and garnet layers in the heterostructure were polycrystalline with random orientation of the crystallites. The thickness of the YBCO and BiDy-IG layers was about 2000 and 4000 Å, respectively, as determined using an atomic force microscope (AFM). Magnetic hysteresis loop measurements and magneto-optic Faraday-rotation technique have been used to determine the orientation of the magnetization in the fabricated thin films.¹¹ A perpendicular

FIG. 1. The resistance of the YBCO/BiDy-IG heterostructure vs temperature measured in demagnetized state in zero magnetic field.

magnetic anisotropy is observed both in the single garnet layers as well as in YBCO/garnet bilayers.

A. dc transport properties of YBCO layer at zero magnetic field

The transport properties of the YBCO layer were characterized by a standard four probe method. Figure 1 shows the dc resistance of the YBCO layer versus temperature at zero magnetic field. The resistance increases with temperature decrease in the interval from 300 down to 90 K, exhibiting typical semiconductor temperature dependence behavior. There is a superconductivity onset around $T_{c \text{ onset}} = 90$ K. Below the $T_{c \text{ onset}}$ point, the resistance falls with decreasing temperatures and finally vanishes at $T_{C|R=0} = 22$ K. This confirms that the YBCO layer experiences the transition (percolation) to the macroscopic superconducting state.

B. Magnetic field effect in the YBCO/BiDy-IG heterostructure

After zero field (FZ) resistance versus temperature measurements, the magnetic field effect measurements were carried out. In these measurements after applying magnetic field for each measurement, the sample has been demagnetized at room temperature, and then zero field cooled to the desirable temperature for the next measurement. At 18 K, when a magnetic field of 0.5 T is applied perpendicular to the surface of the sample, the resistance of the YBCO layer increases from the mΩ range up to 1288 Ω, and the magnetoresistance figure of merit $\Delta R/\Delta H$ (1288 Ω/5000 Oe) reaches the value of 0.26 Ω/Oe. In the wide fluctuation range above $T_{C|R=0}$, the resistance increment $\Delta R = R(T, H) - R(T, 0)$ becomes smaller with the temperature increase. Nevertheless, the magnetic field needed to modulate the superconductivity in YBCO layer becomes smaller as well. Thus, the relatively high figure of merit $\Delta R/\Delta H$ is kept constant over the fluctuation region. For instance, at 77 K, the $\Delta R/\Delta H$ value is still about 0.1 Ω/Oe at applied field of $\Delta H = 2000$ Oe.

A qualitative explanation for the above data would be as follows: The existence both superconducting and semiconducting mixed phases implies there is a Josephson weak link network in the YBCO layer. A dc current passing through

FIG. 2. (a) The inset shows the dc resistance vs temperature with and without remnant magnetization in the BiDy-IG layer. (b) Curve A was measured in the demagnetized state, curve B with the remnant magnetization pointing away from the YBCO layer, curve C with remnant magnetization pointing towards the YBCO layer.

the weak link drives the vortices along the link, which results in energy dissipation and thus a voltage appears across the link.

Vortices start to penetrate into the Josephson junction at the critical field $H_{c1} = (32\phi_0 j_c / \pi^2 c d)^{1/2}$. For granular films with a large intergranular spacing d and a low intergranular critical current density j_c this critical field turns out to be much lower than in the continuous metallic YBCO film. Hence, a relatively small magnetic field can change the film resistance greatly. As j_c is decreasing monotonously with the temperature increase, a weaker magnetic field is needed to modulate the intergranular superconducting state of the YBCO at higher temperatures. Therefore, we arrive to the conclusion that even at temperatures over 77 K, considerable figure of merit $\Delta R/\Delta H$ is still available, which is of great importance for weak magnetic field sensors and SFFT-like device applications.

C. Magnetic memory effect

After demagnetizing, the sample was zero field (FZ) cooled down to 18 K, a 0.5 T magnetic field was applied perpendicular to the sample surface to magnetize the BiDy-IG layer. Then the field was taken away, and the R vs T (curve B) is measured (shown in Fig. 2) to find that $T_{C|R=0}$ is shifted down to 12 K, and below 90 K a distinct shift of the R - T curve is found towards lower temperatures. This implies a *magnetic after-action effect*.

The sample was then demagnetized at room temperature and cooled down to 18 K at zero field. The measured R vs T curve is found to almost coincide with the previous zero field curve A. At 18 K, an opposite 0.5 T magnetic field was applied to change the direction of the remnant moment in BiDy-IG layer and then taken away. In the Fig. 2, it is clearly seen from curve C, that the opposite polarization has almost the same effect as obtained in curve B. This is consistent with the Onsager theorem, but different from the SuFET results, where the opposite direction of the electrical polarization of the ferroelectric layer resulted in up and down shifts of the curves. The effects described above clearly exhibits

FIG. 3. The resistance increment due to the magnetized layer in the YBCO/BiDy-IG heterostructure in the temperature range 20–80 K. $R(M_r)$ and $R(0)$ are the resistances in the remnant and demagnetized states of the BiDy-IG layer, respectively.

magnetic memory, and demonstrates that the remnant moment in BiDy-IG layer can modulate the transport properties of the YBCO layer.

The measured absolute $R(M_r) - R(0)$ and normalized $[R(M_r) - R(0)]/R(0)$ resistance increments versus temperature are shown in Fig. 3. There $R(M_r)$ and $R(0)$ are resistances in the remnant and demagnetized states of the garnet layer, respectively. From the figure, it is easy to see that over a wide temperature range the output voltage increment $\Delta V = V(M_r) - V(0)$ can be achieved from 0.5 to 3.7 mV for a constant current of 10 μ A through the film. Also, the relative voltage increment $\Delta V/V(0)$ is larger than 10%, which is adequate for detection. In order to get large modulation of resistance in high- T_c superconductor/magnetic layer heterostructure, one of the key points is to prepare a oxygen non-stoichiometric YBCO layer to produce a mixture of superconducting and semiconducting phases.

III. CONCLUSIONS

In summary, magnetic field and magnetic memory effects have been observed in the YBCO/BiDy-IG heterostruc-

ture for the first time. The two state behavior, remnant and demagnetized garnet layer, can be easily distinguished by measuring the resistance of the YBCO layer. The observed effect is promising for use in nonvolatile memory applications. In order to achieve significant magnetic after-action effect in high- T_c superconducting layer at relatively weak magnetic fields, a suitable mixture of semi- and superconducting phases is essential. Existence of the semiconducting phase simplifies greatly the device fabrication processing, and various large area and cheap substrates, such as glass become suitable. The operating temperature range of this type of devices is expected to move to much higher temperatures on using Bi- and Hg-based materials with higher T_c .

Spin wave scattering and intermode transitions induced by the magnetic vortex lattice in the ferrite–high-temperature superconductor film structure

L. V. Lutsev^{a)} and S. V. Yakovlev

Research Institute "Domen," Chernigovskaya, 8, St. Petersburg 196084, Russia

A model of dipole-exchange spin wave scattering induced by the periodic magnetic vortex lattice in the in-plane magnetized ferrite–high-temperature superconductor film structure is considered. The vortex magnetic field action leads to spin wave intermode transitions occurring in the ferrite film. It is found that an admixture of the higher mode in the crossing region of the surface spin wave mode with the higher mode (hybrid state) increases the direct intermode transition probability significantly. It is shown that mixing of modes and the formation of hybrid spin wave states depend on the magnetic inhomogeneity over the ferrite film thickness. The theoretical model is verified for a YIG–YBa₂Cu₃O_{7+δ} structure. © 1998 American Institute of Physics. [S0021-8979(98)18811-4]

I. INTRODUCTION

The experimental study of the spin wave propagation in the film structure of a YIG–high-temperature superconductor (HTSC) showed the influence of the magnetic vortex lattice (MVL) on spin wave (SW) scattering.¹ This influence leads to the appearance of absorption peaks on the long-wavelength excitation region of the SW spectrum (SWS). For magnetic fields in the interval $H_{C1} < 10^2$ Oe $\leq H \leq 10^3$ Oe $< H_{C2}$ a type II superconductor (the group to which HTSCs belong) is found in a mixed state.² In this interval the period of the two-dimensional MVL λ is given by the magnetic field and the magnetic flux quantum and is equal to 0.14–0.46 μ m. The wavelength of the spin waves, which was scattered by the MVL, was greater than the vortex lattice period ($> 10 \mu$ m). The appearance of absorption peaks on the SWS cannot be explained by Bragg scattering. The theoretical model of the resonant interaction^{3,4} between long-wavelength spin waves and short-wavelength ones due to the presence of a vortex lattice cannot explain this experimental fact either. The probability of this interaction in homogeneous ferrite films is very small. In the present paper we consider the theory of SW scattering based on intermode transitions. This theoretical model explains the above-mentioned experimental fact. Computer calculations show that the SW-scattering probability is increased significantly when the ferromagnetic film has a specific magnetic inhomogeneity profile through thickness. As a result of this the SW-scattering method can be a very sensitive tool for investigation of the MVL structure.

II. SW-SCATTERING EQUATIONS

We consider a structure consisting of an in-plane magnetized inhomogeneous ferromagnetic film of thickness $2d$ and a HTSC film (Fig. 1). The MVL in the HTSC film is assumed to be composed of interplanar vortices parallel to the y axis and to create a periodic magnetic field $\mathbf{h}_L(x, z, t) \propto \exp(iqx)$, where q is determined by the MVL period: q

$= 2\pi/\lambda$. The spin wave dynamics is governed by the Landau–Lifshitz and the magnetostatic equations,

$$\frac{\partial \mathbf{M}}{\partial t} = \gamma [\mathbf{M} \times (\mathbf{H} - \nabla \varphi + \alpha \Delta \mathbf{M})], \quad (1)$$

$$\Delta \varphi - 4\pi \operatorname{div} \mathbf{m} = 0, \quad (2)$$

where γ is the gyromagnetic ratio, $\mathbf{H} = \mathbf{H}_0 + \mathbf{h}_L$, $\mathbf{M}(t) = \mathbf{M}_0 + \mathbf{m}(t)$, $\mathbf{H}_0 \parallel \mathbf{M}_0 \parallel$ the y axis, φ is the magnetostatic potential of the spin wave, and α is the exchange interaction constant. We write M_0 as the sum of homogeneous and inhomogeneous terms: $M_0(z) = M_0^{(hom)} + \delta M(z)$.

Dropping the derivatives with respect to y and retaining in Eq. (1) the terms linear in $\mathbf{m}(t)$, we obtain

$$B_{\pm} m_{\pm} = \pm i \gamma M_0 D_{\pm} \varphi, \quad (3)$$

where $m_{\pm} = m_x \pm i m_z$, $B_{\pm} = \partial/\partial t \mp i \gamma (H - \alpha M_0 \Delta)$, $D_{\pm} = \partial/\partial x \pm i \partial/\partial z$, and $\Delta = D_+ D_- = \partial^2/\partial x^2 + \partial^2/\partial z^2$.

The requirement that there does not exist a spin wave with $m_{\pm}(x, z, t) \neq 0$ and $\varphi(x, z, t) \equiv 0$ is equivalent to the restriction of the functional space $m_{\pm}(x, z, t) \in C^2((-\infty, \infty), [-d, d], (-\infty, \infty)) \setminus \operatorname{Ker} B_{\pm}$, on which the operators B_{\pm} have inverse operators.⁵ In other words, the functions $m_{\pm}(x, z, t)$ must be orthogonal to the kernel functional space $\operatorname{Ker} B_{\pm}$.

FIG. 1. Ferrite–HTSC film structure. (1), (2)—generator and receiver antennae.

^{a)}Electronic mail: chvv@energo.ru

The use of exchange boundary conditions (spin pinning)^{6,7} is incorrect, since it admits the existence of waves only with a change in the magnetic moment $\mathbf{m}(x, z, t)$.

Substituting m_{\pm} into (2) and assuming the invertibility of B_{\pm} , we obtain the equation for the magnetostatic potential of the spin wave,

$$\Delta\varphi - 2\pi i \sum_{\pm} (\pm D_{\pm} B_{\pm}^{-1} \gamma M_0 D_{\pm}) \varphi = 0. \quad (4)$$

For a homogeneous ferromagnetic film with the magnetic moment density $M_0^{(hom)}$ and without the HTSC film the solutions of Eq. (4) are the wave functions: A. the surface mode $|s\rangle$, for which $D_+|s\rangle=0$ (or $D_-|s\rangle=0$); B. the volume modes,

$$|n\rangle = d^{-1/2} \exp(ik_n x + i\omega_n t) \times \begin{cases} \sin(k_z^{(n)} z + \pi n/2) & z \in [-d, d], \\ 0 & z \notin [-d, d], \end{cases} \quad (5)$$

with the dispersion relation

$$\omega_n = \gamma[(H_0 + \alpha M_0^{(hom)} k_0^{(n)2})(H_0 + 4\pi M_0^{(hom)} + \alpha M_0^{(hom)} k_0^{(n)2})]^{1/2}, \quad (6)$$

where $k_z^{(n)} = \pi n/2d$, $k_0^{(n)2} = k_n^2 + k_z^{(n)2}$, $n=1, 2, 3, \dots$. The set of functions $\{|s\rangle, |n\rangle\}$ is a complete system on $[-d, d]$.

In the case of an inhomogeneous ferromagnetic film with the HTSC film for the SW-scattering analysis it is convenient to single out the proper small terms and to rewrite Eq. (4) in the form

$$\frac{\partial^2 \varphi}{\partial z^2} + A(A + 4\pi\gamma M_0^{(hom)})\varphi + (V_M + V_h)\varphi = 0, \quad (7)$$

where

$$A = \gamma(H_0 - \alpha M_0^{(hom)} \Delta),$$

$$V_M = -2\pi i \gamma \sum_{\pm} [\pm D_{\pm}^{-1} B_{\pm}^{(hom)} \delta M(z) D_{\pm}],$$

$$V_h = 2\pi\gamma^2 M_0^{(hom)} \sum_{\pm} D_{\pm}^{-1} B_{\pm}^{(hom)} h_L(z, x, t) B_{\pm}^{(hom)-1} D_{\pm}.$$

The use of the linear approximation of V_M , V_h in Eq. (7) is justified when $h_L \ll H_0$ and a dispersion curve shift $\delta\omega_n$, induced by V_M , is much less than ω_n in Eq. (6). The perturbation operator V_M leads to the formation of hybrid states, the dispersion curve repulsion at the crossing point and determines the exchange "gaps" observed in the SWS. The perturbation operator V_h governs SW scattering and determines intermode transitions.

III. INTERMODE TRANSITIONS

Let us consider the intermode transition occurring from the hybrid state $|f\rangle = a_s|s\rangle + a_n|n\rangle$ near the crossing point of the dispersion curves of the surface and the volume modes in an inhomogeneous ferromagnetic film (Fig. 2). The perturbation V_h couples modes $|f\rangle$ and $|p\rangle$ having frequencies and wave vectors obeying the conditions

FIG. 2. Direct intermode transitions occurring from the hybrid spin wave states $a_s^{(a,b)}|s\rangle + a_n^{(a,b)}|n\rangle$ near the crossing point of the dispersion curves.

$$\omega_p = \omega_n, \quad k_p = k_n \pm q. \quad (8)$$

To derive the coupling equations we seek a solution in the form

$$\varphi = C(t)|f\rangle + F(t)|p\rangle. \quad (9)$$

Substituting (9) into (7) and keeping terms of first order, we obtain coupling equations for slowly varying amplitudes $C(t)$, $F(t)$,

$$\begin{aligned} \frac{\partial C(t)}{\partial t} &= \frac{i}{2\omega_n} \langle n|V_h|p\rangle F(t), \\ \frac{\partial F(t)}{\partial t} &= \frac{i}{2\omega_p} \langle p|V_h|n\rangle C(t). \end{aligned} \quad (10)$$

For $F(t) \ll C(t)$ the probability of an intermode transition over a time τ is found from Eq. (10)

$$\begin{aligned} P_{pf} &= \frac{F^2(t)}{C^2(t)} = \left| \frac{1}{2\omega_p} \int_0^\tau \langle p|V_h|f\rangle dt \right|^2 \\ &= \left| \frac{\pi\gamma^2 M_0^{(hom)}}{\omega_p k_0^{(p)2}} \sum_{\pm} \int_0^\tau \left[B_{\pm}^{(p,hom)} \right. \right. \\ &\quad \times \langle p|D_{\pm} h_L D_{\pm}(|s\rangle a_s B_{\pm}^{(s,hom)-1} \\ &\quad \left. \left. + |n\rangle a_n B_{\pm}^{(n,hom)-1}) \right] d\tau \right|^2, \end{aligned} \quad (11)$$

where $B_{\pm}^{(l,hom)} = i\omega_l \mp i\gamma(H_0 + \alpha M_0^{(hom)} k_0^{(l)2} \delta_l)$, $\delta_l=0$ for $|s\rangle$ and $\delta_l=1$ for $|n\rangle$, and the integration in $\langle p|V_h|f\rangle$ is over x, z of the film volume.

The existence of the second summand in Eq. (11) with $B_{\pm}^{(n,hom)-1} \gg B_{\pm}^{(s,hom)-1}$ leads to a sharp increase in the probability of the intermode transition from hybrid states. Conversely, the presence of hybrid states depends on the inhomogeneity of the ferromagnetic film.

IV. CALCULATIONS AND EXPERIMENT

We define the spin wave spectrum SWS as the frequency dependence of the square of the ratio of currents in the receiver and generator antennae: $W = (J_{rec}/J_{gen})^2$. J_{rec} is proportional to the sum E_{rec} of the induced electromagnetic signal E_e and two signals of spin waves (Fig. 2) with amplitudes $C^{(a,b)}(\tau_l)$

$$E_{rec} = \{E_e + [C^{(a)}(\tau_l)\exp(ik_n^{(a)}l) + C^{(b)}(\tau_l)\exp(ik_n^{(b)}l)] \times \exp(-\gamma\Delta H\tau_l)\}\exp(i\omega_n t), \quad (12)$$

where $C^{(a,b)}$ should be found from Eq. (10), l is the space between the antennae, $\tau_l = l(\partial\omega/\partial k)^{-1}$ is the spin wave propagation time between the antennae, and ΔH is the relaxation parameter. We have calculated SWS using Eqs. (7) and (11) for a YIG film (for $2d = 14\mu\text{m}$) and taking into account three assumptions:

A. The YIG film has the linear variation of M_0 from $M_0^{(hom)}$ to 0 over the sublayer of thickness $0.5\mu\text{m}$ near the substrate. This assumption gives operator V_M in Eq. (7) and determines the dispersion curve repulsion.

B. $h_L(z, x, t) = H_0 \exp[iqx + q(z - d - \lambda/2)]$. It gives the form of the SW scattering.

C. The MVL period $\lambda \propto H_0^{-1/2}$.

We have obtained the following results.

1. Absorption peaks are observed only in the region of the crossing point of the dispersion curves of the surface $|s\rangle$ and the volume $|n\rangle$ modes. Conditions (8) must be realized.

2. A greater value of H_0 leads to the observation of peaks with greater n .

3. If n is fixed, the transition $|f\rangle = a_s|s\rangle + a_n|n\rangle \rightarrow |p\rangle$ with $p=1$ gives the absorption peak with the maximal H_0 .

4. The MVL period can be found by $\lambda = 4d/\sqrt{n^2 - p^2}$.

These dependences have been observed in the experiment. The experiment has been undertaken in the heterostructure of a YIG film of thickness $14\mu\text{m}$ and a monocrystal HTSC film $\text{YBa}_2\text{Cu}_3\text{O}_{7+\delta}$ of thickness $0.5\mu\text{m}$ on a MgO substrate (Fig. 1). l is equal to 7.8 mm . Figure 3 shows the absorption peak on the SWS at 3.17 GHz ($H_0 = 363\text{ Oe}$) with

FIG. 3. Spin wave spectrum of the ferrite-HTSC film structure at $H_0 = 363\text{ Oe}$.

$n=66$, $p=1$. The MVL period λ is equal to $0.42\mu\text{m}$. This value is a little greater than the lattice constant in volume samples defined by the quantum of the magnetic flux $\psi = 2.07 \times 10^{-7}\text{ Oe cm}^2$: $\lambda_0 = \sqrt{\psi/H_0} = 0.239\mu\text{m}$. The increase of the lattice parameter may be explained by the influence of the surfaces of the films.² In the next paper we intend to consider in more detail experiment verification of the present theoretical model.

Magnetic dissipation force microscopy studies of magnetic materials (invited)

Y. Liu and P. Grütter^{a)}

Centre for the Physics of Materials, Department of Physics, McGill University, Montréal, Québec, H3A 2T8 Canada

We describe the principles of dissipation measurements, discuss various eddy current damping mechanisms, give a brief review of a model for magnetoelastic dissipation due to domain-wall width oscillations, and present some applications of magnetic dissipation force microscopy to magnetic materials. Energy dissipation is measured by simultaneous monitoring of the damping of an oscillating cantilever and the shift in resonant frequency in a magnetic force microscope. Magnetoelastic dissipation is caused by tip-field-induced domain-wall width oscillations through magnetostriction effects. Magnetoelastic damping is strongly correlated with micromagnetic structures and allows different domain walls (such as Bloch and Néel walls) to be distinguished.

© 1998 American Institute of Physics. [S0021-8979(98)48611-0]

Magnetic dissipation force microscopy¹⁻⁴ is a working mode of an ac magnetic force microscope (MFM). In this mode, the magnetic tip oscillating at resonance serves as both force gradient and dissipation sensor. Energy dissipation causes damping of the oscillating tip and is measured by monitoring the oscillation amplitude.

This new working mode of the ac MFM directly measures the local magnetic energy dissipation with lateral resolution at least as good as the normal MFM. We do this by measuring the damping of the oscillating tip in a MFM simultaneously with the usual frequency shifts associated with tip-sample force gradient variations. A change in damping of the MFM probe is the result of energy transferred between the tip and the sample and is detected as a difference in cantilever oscillation amplitude. Damping due to Joule dissipation in semiconductors has previously been measured with a different detection scheme by Denk and Pohl.⁵

In the ac MFM, a magnetic tip is vibrated above a sample surface and creates a local alternating magnetic field at the sample, resulting in energy dissipation in the sample. The thin-film tip stray field, which contains a dc part and an ac part, is concentrated on a region of the sample 50–500 nm in diameter, depending on the tip shape and tip-sample separation.² By using this highly localized tip field and measuring the resulting energy dissipation, we can quantitatively determine the local effect of the tip field on the micromagnetic structure of the sample.

We measure the damping γ or equivalent quality factor Q change of the cantilever, which can be described by a driven damped harmonic oscillator ($\gamma = k_l / \omega_0 Q$). Here, k_l is the cantilever spring constant and ω_0 is the resonant frequency of the cantilever. At resonance, the vibration amplitude is $A = (F_0 / \omega_0) Q_0$, where F_0 is the driving amplitude

(proportional to the ac voltage applied to the piezoelectric bimorph) and Q_0 is the quality factor of the cantilever. Magnetic dissipation in the sample causes an energy loss in the cantilever and so reduces the Q factor. A larger driving force is thus needed to keep the vibration amplitude constant. The extra force is given by

$$\Delta F = -(F_0 / Q_0) \Delta Q. \quad (1)$$

The energy loss (dissipation) in one cycle is then

$$\Delta E = -(E_k / Q_0^2) \Delta Q. \quad (2)$$

Here, $E_k = (1/2) k_l A^2$ is the vibration energy of the cantilever with k_l the spring constant of the cantilever.

We can thus measure the energy loss (dissipation) by measuring the driving force change while keeping the cantilever vibrating at resonance with a constant amplitude if we ensure that any phase shifts are negligible. By recording the driving signal changes simultaneously with the usual frequency shifts associated with tip-sample force gradient variations, a normal MFM image and a dissipation image can be acquired simultaneously. This allows the study of correlations between magnetic dissipation and domain structure. In the following, we will use ΔQ in our discussion. ΔQ can easily be transformed to ΔE or $\Delta \gamma$.

We employ the same phase-locked loop (PLL) demodulator⁶ to track both the resonant frequency and the driving force of the cantilever. When the PLL is locked to the cantilever resonance, it will always keep the cantilever vibrating on resonance and at a constant vibration amplitude by adjusting the driving amplitude to compensate for any damping. This is achieved with an additional feedback circuit to keep the cantilever's vibration amplitude constant at a preset value. A dc voltage proportional to the cantilever's vibration amplitude is compared with a set value and the difference signal is integrated. The output signal of the inte-

^{a)}Electronic mail address: grutter@physics.mcgill.ca

grator will determine the driving signal amplitude to a piezoelectric bimorph, which excites the cantilever. The integrator output serves as the signal for dissipation images.

The fundamental limit for the detection of a Q -factor change δQ , assuming that the displacement measurement is limited only by the cantilever's thermal motion, is given by

$$\delta Q_{\text{thermal}} = \frac{1}{A} \sqrt{\frac{2k_B T Q^3 B_W}{k_l \omega_0}}, \quad (3)$$

with k_B being the Boltzmann's constant, T being the temperature, and B_W being the measurement bandwidth. For our cantilevers ($k_l = 0.1$ N/m, $f_0 = 30$ kHz, and $Q = 1000$ in vacuum) $\delta Q_{\text{thermal}} = 5.3$ (which corresponds to a $\delta \gamma_{\text{thermal}} = 2.8$ pNs/m or $\Delta E = 1.0 \times 10^{-3}$ eV, respectively) with $B_W = 35$ Hz and $A = 25$ nm. All our dissipation data are thermally limited. A better signal-to-noise ratio is predicted, and indeed, observed by measuring dissipation in vacuum. All of the data presented here were obtained at 5×10^{-5} mbar.

Minimizing the phase error between the cantilever oscillation and its drive signal is crucial to obtaining a meaningful damping measurement. Phase errors (e.g., due to filters) will drive the cantilever off-resonance. A larger drive amplitude F' would then be necessary to maintain a constant amplitude, which would falsely be interpreted as a change in cantilever damping. The Q -factor error δQ , due to phase error $\delta \phi$, is given by

$$\delta Q_{\text{Phase}} \approx \frac{1}{2} Q (\delta \phi)^2. \quad (4)$$

Our carefully optimized electronics maintain a phase error of less than 0.003 rad for frequencies between 10 kHz and 2 MHz. This amounts to an error of $\delta Q < 0.005$ for $Q_0 = 1000$, substantially smaller than the thermal limit. A second source of phase shifts is frequency feedback errors, e.g., as a result of varying force gradients between tip and sample. The influence of frequency error on the drive output can directly be measured by modulating the PLL reference frequency. We determined $\delta Q < 0.004$ for a 10 Hz modulation in vacuum. In our experiments, the frequency feedback errors are kept smaller than 2 Hz, resulting in $\delta Q < 0.001$. A further potential phase error is particular to our fiber-optic interferometric deflection sensing technique. Dc deflection Δz as a result of forces acting on the cantilever will result in an optical path-length difference, and thus, a phase-shift $\Delta \phi = (2\Delta z/\lambda)2\pi$. In our experiments we monitor this deflection simultaneously with the damping and the force gradient signal. The maximum total deflection is always smaller than 1 nm, and thus, introduces a phase error of 0.01, resulting in an error of $\delta Q < 0.05$.

A further potential error in damping measurements is due to the tip-sample separation dependence of the hydrodynamic cantilever damping observed in air.⁷ Typically, Q changes larger than the thermal limit are observed for tip-sample separation changes of a few nm if the average separation is 50 nm or less. To avoid the potential convolution of the regular MFM (acquired at variable tip-sample separation as $F' = \text{const.}$) and dissipation data, we always acquire our dissipation data in vacuum, where a separation-dependent Q factor is not observed for tip-sample separations larger than several nm.

In conclusion, by carefully designing and characterizing our PLL, keeping feedback errors to 2 Hz, and controlling phase errors due to optical path-length changes and vacuum operation, we are confident that all measured drive amplitude changes are only due to changes in the magnetic damping of the cantilever.

The following loss mechanisms due to eddy and induced currents can be identified:

- (1) Eddy currents in the sample due to oscillations of the domain-wall position. An ac magnetic field may lead to domain-wall oscillations around the wall equilibrium position, generating eddy currents around the oscillating domain walls.
- (2) Eddy currents in the MFM tip due to the stray field from the sample. When the tip is oscillating, the sample stray field generates eddy currents in the tip.
- (3) Eddy currents in the tip due to tip magnetization changes. When the tip is oscillating, the gradient of the sample stray field may induce tip magnetization change dM/dt , which generates eddy currents in the tip.
- (4) Eddy currents in the sample due to tip field. An oscillating tip creates an alternating magnetic field at the sample, thus leading to magnetic-flux changes in the sample. For a conducting sample, eddy currents are induced in the sample.
- (5) Eddy currents in the sample due to domain-wall jumps.
- (6) Induced currents in the sample due to capacitance changes between the tip and sample. The capacitance of the tip-sample system oscillates as a result of the tip oscillation. If a constant voltage is applied between the tip and the sample (as in our instrument for servopurpose⁸), the oscillating capacitance leads to an alternating current as a result of alternating charge redistribution. Variations in magnetoresistance could thus lead to magnetic contrast. This source of damping is not related to eddy currents.

We have theoretically calculated and experimentally tested the contributions of eddy current losses (1), (2), and (3) to the damping of a Si cantilever (coated with 20 nm CoNi film) and a Si_3N_4 cantilever (coated with 90 nm CoPtCr film) on several samples (30 nm thick patterned $\text{Ni}_{80}\text{Fe}_{20}$ film, 4 nm thick Co film, and 40 nm thick CoPtCr film) and found that these contributions are far too small (by 4–6 orders of magnitude) to explain the observed damping signal.^{2,3} The damping signals due to losses (4) and (6) depend on the resistivity of the sample. The dissipation due to induced currents (6) is proportional to the sample's resistivity and can be used to determine dopant concentration in semiconductors.⁵ The resistivity of the metallic samples is low (for cobalt it is $9.8 \times 10^{-8} \Omega \text{ m}$), which leads to a dissipation signal that is below the thermal limited minimum detectable resistivity change of about $4 \times 10^{-3} \Omega \text{ m}$.⁵ The small variations of resistivity due to magnetoresistive effects (typically, $\Delta R/R < 1\%$) do not lead to a measurable dissipation contrast. The dissipation due to eddy current (4) is an inverse measure of resistivity. However, a dissipation measurement on a patterned permalloy film on a Si substrate¹ shows that the background dissipation signal on the permal-

loy area (with a resistivity on the order of $10^{-7} \Omega \text{ m}$) is smaller than in the Si area (with a much higher resistivity). The permalloy background signal corresponds to the thermal limit, in contrast to the observed resistive dissipation on Si. We conclude that the effect of the induced current (6) is larger than that of the eddy current (4) in this sample. Due to the very short time scales involved in domain-wall jumps, eddy currents (5) might lead to some dissipation contrast.³ In wall jumps (induced by the tip field), the wall speed can be extremely high, resulting in substantial, but difficult to quantify, eddy current losses.

In conclusion, all eddy current related processes, with the exception of tip-induced domain-wall jumps, lead to dissipation values not measurable in vacuum with our standard MFM tips.

A magnetoelastic model for dissipation, which bases the dissipation on domain-wall width oscillations and the resulting phonon emission through the magnetostriction effect, has given quantitative agreement with experiments on samples investigated in detail.^{2,4} The domain-wall width oscillations $W(t)$ can be treated as a simple harmonic oscillator described by an equation, which contains an inertia term $m\ddot{W}$, a stiffness force $\alpha(\Delta W)$, a damping term,⁹ and an external alternating driving force term related to the external ac tip field. Here, m is the effective mass of the domain wall for width oscillations and α is the wall stiffness of the domain wall for width oscillations. In most problems, damping terms are considered to be viscous in nature (i.e., the damping force is proportional to velocity). However, for magnetoelastic loss, the damping of wall width oscillations appears to be frictional in nature since the elastic energy changes associated with the wall width change only depend on the magnitude of the wall width change and not on the rate of the width change. Hence, the damping term can be written as $-\beta\dot{W}/|\dot{W}|$. The equation of motion for wall width oscillations is then

$$m\ddot{W} + \beta \frac{\dot{W}}{|\dot{W}|} + \alpha(W - W_0) = F, \quad (5)$$

where W_0 is the equilibrium width of the domain wall and $F = F_0 \exp(i2\pi ft)$ is the force trying to oscillate the wall width.

The parameters m , α , β , and W_0 have been derived and expressed in basic magnetic properties of magnetic materials⁴ with $m = \pi\mu_0/48\gamma^2 W_0$, $\alpha = K_1/W_0$, $\beta = \frac{1}{2}c\lambda^2$, and $W_0 = \sqrt{2JS^2\pi^2/K_1\alpha}$, assuming that the demagnetization energy of the wall can be neglected. Here, K_1 is the anisotropy constant; c is Young's modulus; λ is the magnetostriction constant; J is the exchange integral; S is the spin; a is the unit cell length; and γ is the gyromagnetic ratio. The driving force for wall width oscillations F was found to be strongly dependent on the relative orientation of the mean-magnetization direction inside a domain wall and the external magnetic field. For a Bloch wall $F = \pm(2\mu_0 M_s H_z/\pi)$, depending only on the out-of-plane component of the external tip field, while for a Néel wall F is related to the in-plane component of the external tip field. In magnetic dissipation force microscopy, the external field is created by an oscillat-

ing magnetic tip and is highly localized. Thus, different micromagnetic structures in a domain wall will result in dissipation contrast for a given tip. Letting $F = F_0 \exp(i2\pi ft)$ and $W = W_0 + W_1 \exp[i(2\pi ft + \delta)]$ (f is the oscillation frequency of the tip), we can obtain the energy dissipation in one oscillation cycle as

$$P = 4f\beta W_1 = 4f\beta \frac{\sqrt{F_0^2 - \beta^2}}{\alpha - (2\pi f)^2 m}. \quad (6)$$

Quantitative agreement between this equation and experiments for a Co film sample and a Co/Ni multilayer sample was previously obtained.^{2,4} Furthermore, by comparing permalloy and Terfenol-D (which has a much higher λ than permalloy), we observed the expected relative dissipation increase in the Terfenol-D sample. In addition to this agreement, the model predicts a wall width resonance. The resonant frequency for the Co sample was calculated to be on the order of 10^{10} Hz .⁴ Hence, the wall width resonance might influence the high-frequency properties of magnetic materials.

An interesting consequence of Eq. (6) is that a minimum driving force is necessary to observe dissipation. By engineering suitable tips (e.g., by selecting a thin, low moment coating), a small F_0 can be created, thus inhibiting energy loss due to domain-wall width oscillations. The absence or presence of nonconservative tip-sample interactions (at least above the thermal limit) can thus be monitored by dissipation force microscopy.

Magnetic dissipation force microscopy has been used to study the magnetic domain structures of several samples, including a patterned permalloy film,^{1,4} and transitions in a CoPtCr magnetic recording medium,¹ Co/Ni multilayer,² and Terfenol-D.^{1,4} The experimental dissipation showed discontinuous change along domain walls in the patterned permalloy film.¹ This suggests that there are different micromagnetic structures in the domain walls. Figure 1 shows a high-resolution MFM image and the simultaneously acquired magnetic dissipation image on a part of one permalloy square. It can be seen from Fig. 1(a) that the magnetic domain walls in this permalloy are not pure Néel or pure Bloch walls. They contain complicated micromagnetic structures, possibly Bloch points and Bloch lines. We observe that on the same sample but for different squares, domain walls have different micromagnetic structures. In Fig. 1(b) the long micromagnetic features (indicated by the arrows), which cross the main wall and connect the two adjacent magnetic domains, are formed by finer identical spots. Black and white spots are observed. They show opposite signs of magnetic tip-sample interactions. Other domain walls even on the same square show less magnetic substructure [top left of Fig. 1(a)].

Figure 2(a) gives another example of a domain-wall structure observed on the permalloy film. Here, there are fewer internal micromagnetic features inside the main domain wall, which shows up as a bold dark line from the lower-left corner to the upper-right corner (the bold white line on the left side of the image is the edge of the permalloy square). However, one observes a lot of ripplelike magnetic features, which are perpendicular to and terminated at the

FIG. 1. High-resolution MFM and magnetic dissipation images on a permalloy square with a 20 nm CoNi film coated Si tip. The MFM image is differentiated along the fast scan direction to enhance the contrast. (a) is the $12\ \mu\text{m} \times 12\ \mu\text{m}$ MFM image, (b) is the enlarged area shown by the rectangle in (a), and (c) is the magnetic dissipation image of the same area as (b).

main wall position. Ripples in permalloy films are commonly observed¹⁰ and have been observed by MFM.¹¹ Figure 2(b) is the simultaneously acquired dissipation image, which shows again that the dissipation signal is associated with some of the magnetic wall features. There is a magnetic feature (indicated by an arrow), which leads to a pronounced dissipation signal (about 0.03 eV in one oscillation cycle), and is not part of the main wall. A reproducible jump of this magnetic feature is observed as a highly localized change in dissipation on several scan lines indicated by an arrow in Fig. 2(b). By applying a field of only 2 Oe with an *in situ* electromagnet, this feature disappears while the main wall is displaced by less than $1\ \mu\text{m}$, confirming that the feature is magnetic in origin.

The existence of different micromagnetic domain-wall structures of the permalloy film suggest that there are many wall configurations which have very similar energy minima. In order to advance our understanding of the micromagnetic wall structures and the associated magnetic dissipation in patterned permalloy films, micromagnetic calculations are needed. Such calculations are not presently feasible for sys-

FIG. 2. Ripplelike magnetic features intersect with this main wall in a permalloy film. The image area is $8\ \mu\text{m} \times 4\ \mu\text{m}$. (a) differentiated MFM image. The domain wall is the black structure running diagonally across the image. The white vertical line to the left of the image is the edge of the permalloy square. (b) Magnetic dissipation image.

tems as large as the $20\ \mu\text{m}$ squares. Clearly, however, dissipation imaging opens the possibility of characterizing a variety of micromagnetic structures.

For this study, we used our home-built high-resolution magnetic dissipation force microscope (MDM) with an *in situ* magnetizing stage. The magnetizing stage is also home-built¹² and the field (in the sample plane) can be changed continuously from -1 to $+1$ kOe. The MFM and MDM images are taken simultaneously as a function of this external magnetic field. Prior to experiments, the sample is saturated and then ac demagnetized. The procedure for changing the field follows the macroscopic $M-H$ hysteresis loop. We first increase the field from zero to saturation and then decrease it to zero. An opposite field is then applied to the opposite saturation value and decreased to zero again. The procedure is then finished by again changing the sign of the field and increasing it to the first saturation value. The field is changed in small steps. After each of these steps, a MFM and a MDM image are taken simultaneously. For each experimental run, typically, 20–30 images are taken and assembled as a video to allow easier observation of changes between field steps.

Figure 3 shows the evolution of the domain configuration with decreasing magnetic field after saturating along one edge of the permalloy square. Figure 4 gives the simultaneously acquired dissipation images. The image of the permalloy is not square due to uncorrected piezo-nonlinearity.

The saturation field is 90 Oe for the patterned permalloy film, at which no contrast is observed in either MFM or dissipation images. This saturation field here is much higher than for a film of the same thickness, but infinite extent in the plane of the film (which has a coercivity of around 2 Oe). The higher saturation field in the patterned film is due to demagnetization effects, since for an external field larger than 10 Oe the domain walls are concentrated at the edge area of the squares. A much higher external field is needed to

FIG. 3. Evolution of the domain configuration with decreasing magnetic field after saturating along one edge of the permalloy square. The field direction is indicated in (a). (a)–(f) are taken consecutively with the *in situ* applied field shown in the individual images. The inset in each individual image depicts the proposed domain structure.

remove these domain walls. On decreasing the field, magnetization reversal takes place first by reverse-domain nucleation at one edge at a field of 68 Oe [Figs. 3(a) and 4(a)]. Note that although nucleation is not seen in the regular MFM image, it is clearly seen in the dissipation image. Hence, dissipation imaging allows the observation of early stage domain nucleation especially at sample edges, where other magnetic imaging techniques have major problems. On decreasing the field further, the reverse domain grows [as indicated by a solid arrow in Fig. 3(c)] with its magnetization direction probably perpendicular to the external field (parallel to the edge). At $H = 13$ Oe, a new domain with a magnetization direction antiparallel to the external field (parallel to one edge of the sample) is formed. Figures 3(b), 3(c), and 3(d) also show a long magnetic structure (indicated by a dashed arrow) starting from the right corner of the square. This structure, becoming longer with decreasing external field, is believed to be a 360° wall (simulations of the expected MFM response of a 360° wall are comparable with experimental results).³ At $H = 5$ Oe, all the four domains with parallel, antiparallel, and perpendicular magnetization with respect to the external field are present. For this configuration to be achieved, a domain rotation from the exter-

FIG. 4. Evolution of the dissipation configuration with decreasing magnetic field after saturation along one edge of the permalloy square. (a)–(f) are simultaneously acquired with (a)–(f) of Fig. 3, respectively.

nal field direction to a direction perpendicular to the field (parallel to the edge) must have occurred when the long magnetic structure meets other domain walls. The exact field at which this happens could not be determined. Possibly, this might be due to the limited time resolution of our nonoptimized imaging (each image takes 10–20 min). The rotated domain is indicated in Fig. 4(e) by an arrow. Inside this rotated domain, another long magnetic structure is seen, which disappears when the external field is reduced to zero. At this point, the four domains become equal in size and the edge effect driven closure domain configuration is formed. The magnetic domain structure in Fig. 4(f) differs from the ac demagnetized sample in that the magnetic ripples appear only on two edges of the sample instead of on all the four edges.¹ The magnetization direction of the two domains, which shows magnetic ripples, is either parallel or antiparallel to the previously applied field.

The magnetic dissipation signals (Fig. 4) show maxima always associated with domain-wall positions during the reversal.

Applying an external magnetic field does not move some structures [e.g., the “crater” in the middle of the square and the bright spots outside the square in Fig. 4(a)]. This indicates that they are topography that was not served out and

FIG. 5. Constant force gradient and magnetic dissipation images of an Fe/Cu multilayer (GMR) sample. Image size is $5\ \mu\text{m}$ by $2.9\ \mu\text{m}$. The average tip-sample separation is 60 nm. (a) and (b) are the constant force gradient and the simultaneously acquired dissipation images in the absence of an external field. (c) and (d) are the constant force gradient and the simultaneously acquired dissipation images in the presence of an external field of 30 Oe on the same area as (a). Maximum z variations in both (a) and (c) are all 1 nm. The variation of driving amplitude in (b) is 70 mV (corresponding to an energy loss of 0.019 eV in one oscillation cycle, $Q_0 = 10\ 000$ for this experiment), while in (d) it is 18 mV (thermal noise level). The average driving amplitude for (b) and (d) is 3000 mV. No image processing except for a plane subtraction was performed for the constant force gradient images. The dissipation images are raw data.

provided convenient markers that were independent of the magnetic structures.

In multilayer GMR samples (consisting of alternative nonmagnetic and magnetic layers), the adjacent magnetic layers are antiferromagnetically coupled through a Ruderman-Kittel-Kasuya-Yosida interaction.¹³ A single nonmagnetic or magnetic layer has a typical thickness of only several angstroms. As a result, the sample stray field at positions thousands of angstroms above the sample surface is virtually zero since the fields from the adjacent magnetic layers cancel each other. This raises a challenge to image the magnetic domain structure in these samples by normal magnetic force microscopy, which relies on the interaction between the tip magnetization and sample stray field. Figures 5(a) and (b) show the experimental results on a (Cu 25 Å/Fe 11 Å)×36 multilayer GMR sample at $z = 60$ nm. The contrast in Fig. 5(a) comes from the sample surface topography while the contrast in Fig. 5(b) is a result of tip stray field influencing the sample magnetic structure. We verify this by imaging with an external field. At a field of 30 Oe parallel to the sample surface (the sample's coercivity is 3 Oe), the contrast in the dissipation image [Fig. 5(d)] disappears while the constant force gradient image [Fig. 5(c)] is unchanged. The signal observed in Fig. 5(d) corresponds quantitatively to the thermal noise limited dissipation measurements. Magnetic dissipation microscopy can thus detect magnetic structures not observable by magnetic force microscopy. This might have future applications in investigating antiferromagnets, spin glasses, and patterned magnetic media as well as in high-density storage if data rates and reliability issues can be solved.

Further studies on the origin of the dissipation in the GMR samples might help to determine the interlayer coupling strength and micromagnetic structure in these samples.

In conclusion, the nonconservative interaction of the tip stray field with micromagnetic structures can be deduced by measuring dissipation in an ac MFM. We find that the major contribution to magnetic dissipation originates in magnetoelastic losses as a result of the tip-field coupling to the sample magnetization. Dissipation measurements are thermally limited. We have achieved a sensitivity of better than 2.0×10^{-4} eV/ \sqrt{Hz} per oscillation cycle of the tip in a vacuum MFM. Lateral resolution in dissipation imaging is at least as good as standard MFM imaging. Quantitative dissipation measurements in combination with micromagnetic simulations should allow an upper boundary to be put on the influence of the tip stray field on the switching behaviors of small magnetic particles. Dissipation measurements allow us to determine the onset of tip influences on the micromagnetic structures long before they are observable in regular MFM. Dissipation also allows us to distinguish between different micromagnetic wall structures such as Néel and Bloch walls, Bloch lines, etc. Furthermore, the presence of domain walls can be deduced with dissipation measurements when standard MFM fails, such as at the edges of permalloy samples (large topography variations) or when the sample stray field is very weak (e.g., in antiferromagnetically coupled multilayer thin-film structures). Quantitative dissipation imaging on a suitable reference sample can also be used as a relative calibration of tip stray fields, an important parameter in qualitative and quantitative interpretation of MFM data.

The magnetic structure and dynamics in the colossal magnetoresistance (CMR) class perovskite $\text{La}_{0.53}\text{Ca}_{0.47}\text{MnO}_3$ have been studied by elastic and inelastic neutron scattering. This composition is near the 0.5 Ca transition from a metallic ferromagnet to an insulating antiferromagnet. Powder neutron diffraction on these samples showed coexisting ferromagnetic and antiferromagnetic phases at low temperature and a splitting of the lattice parameters of the antiferromagnetic phase near T_N , reflecting the onset of the charge ordered state. Inelastic scattering measurements of the ferromagnetic excitations exhibited well-defined spin waves of resolution width below T_c . The spin waves exhibited conventional Heisenberg behavior with dispersion of the form $E = Dq^2 + \Delta$ with spin stiffness $D(T=0\text{ K}) \approx 135\text{ meV \AA}^2$ and an energy gap $\Delta \approx 0.1\text{ meV}$. The value of the spin wave stiffness D is similar to that found for other ferromagnetic perovskite materials, and it renormalized with temperature in a manner consistent with the magnetization. © 1998 American Institute of Physics. [S0021-8979(98)27211-2]

I. INTRODUCTION

The discovery in the early 1990s of a colossal magnetoresistance effect¹ (CMR) in perovskite manganite compounds and their potential technological applications has sparked an intense revival of interest in the magnetic properties of these materials, for which the basic magnetic and crystal structure data date back to 1955.² Key to the understanding of the magneto and transport properties of the compounds is the relationship of Mn^{+3} – Mn^{+4} double exchange interactions, Jahn–Teller distortions, polarons, and charge ordering. Inelastic neutron scattering provides a mechanism to study these mechanisms via their influence on the spin wave excitations, including anomalous dispersion effects, spin diffusion central modes, and unusual spin wave lifetimes.

The $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ system exhibits metallic ferromagnetism above a threshold value of $x \approx 0.2$ and above $x \approx 0.5$ becomes an insulating antiferromagnet. Previous magnetization and transport results have indicated³ that compositions between $x=0.47$ and $x=0.50$ exhibit concomitant ferro and antiferromagnetic states with the ferromagnetic transition temperature approximately 40 K higher than the antiferromagnetic transition temperature for $x=0.48$. The onset of the antiferromagnetic state is accompanied by charge ordering of the Mn^{+3} and Mn^{+4} on distinct lattice sites and is reflected in a splitting of the lattice parameters ascribed to Jahn–Teller distortions of the Mn^{+4}O_6 octahedra.⁴ In this article we present neutron results on the magnetic structure and spin dynamics measured in a polycrystalline sample of

$\text{La}_{0.53}\text{Ca}_{0.47}\text{MnO}_3$. This composition was chosen to examine the nature of the coexistence of ferro and antiferro order and the effect of this coexistence on the ferromagnetic spin excitations.

The crystal structure, confirmed by neutron powder diffraction, was indexed as a slightly orthorhombic $Pnma$ space group at room temperature with an additional monoclinic $P2_1/m$ structure at low temperature amounting to a 40% volume fraction. The magnetic refinement confirmed the coexistence of both ferromagnetic and antiferromagnetic phases below T_N that persisted down to 10 K, the lowest temperature measured. The low T values of the Mn moment were $2.8\mu_B$ for the ferromagnetic phase derived from the orthorhombic crystal phase, and $3.7\mu_B$ for the Mn^{+3} and $2.8\mu_B$ for the Mn^{+4} site of the monoclinic phase. The latter phase exhibited a change in lattice parameters near T_N reflecting the onset of charge ordering.

II. MAGNETIC INELASTIC SCATTERING

Lynn *et al.*^{5,6} have studied the spin dynamics in the CMR optimally doped composition $\text{La}_{0.66}\text{Ca}_{0.33}\text{MnO}_3$ and have found marked departures from conventional Heisenberg spin wave behavior. They observed a quadratic dependence of the spin wave energy on wave vector transfer ($E_{\text{sw}} = Dq^2 + \Delta$) as expected with no measurable energy gap Δ at $E=0$. However, the spin stiffness D , which usually mimics the magnetization, showed only a relatively weak renormalization with temperature of approximately 50% up to T_c . Spin waves were not observed above T_c ; however, an anomalous large central (elastic) mode developed above about 80% of T_c that persisted to temperatures well in excess

FIG. 1. Spin wave spectra for $q=0.06 \text{ \AA}^{-1}$ at 150 and 200 K. Data taken at 10 K have been subtracted to remove parasitic scattering near $E=0$.

of T_c . This central mode was observed to exchange spectral weight with the spin wave excitations, and to have a width varying with q^2 indicative of spin diffusion.

In the present work, inelastic scattering data were taken on a powder sample of $\text{La}_{0.53}\text{Ca}_{0.47}\text{MnO}_3$ from 240 K ($T_c \approx 237 \text{ K}$) down to 10 K using a triple axis spectrometer at the University of Missouri Research Reactor. The incident neutrons derived from a focused (002) pyrolytic graphite monochromator had energy of 14.2 meV. A pyrolytic graphite analyzer was used with Soller slit collimations of $10' - 10' - S - 10' - 10'$ before and after the monochromator and analyzer. Due to the polycrystalline form of the sample, inelastic data could only be taken in the first Brillouin zone about the (000) reflection. At these low scattering angles, the range of energy transfers that could be measured for each q is significantly restricted by kinematic considerations, and in general only the longer wavelength spin waves can be examined, which must be assumed to be isotropic in q . The spectrometer configuration gave a resolution for elastic scattering of 0.2 meV, and due to focusing conditions that are nearly identical for neutron energy gain and loss peaks at low q , the intrinsic spin wave widths are somewhat narrower.

Constant q -mode inelastic scattering data were taken at a number of q s in the range $0.04 \text{ \AA}^{-1} \leq q \leq 0.1 \text{ \AA}^{-1}$ at each temperature and over both positive (neutron energy loss) and negative (neutron energy gain) maximum energy ranges dictated by the kinematic restrictions. Figure 1 shows the results of constant $q=0.06 \text{ \AA}^{-1}$ inelastic scans at 150 and 200 K (the ferromagnetic $T_c=237 \text{ K}$). The increased statistical error near $E=0$ results from the subtraction of data taken below 10 K, which effectively suppresses the parasitic incoherent elastic scattering from the cryostat and from the sample.

FIG. 2. Plot of the spin wave energies vs q^2 showing the quadratic dispersion and the existence of a small $q=0$ energy gap.

At 10 K, thermal population effects produce negligible spin wave scattering. (It is noted that the $E=0$ parasitic scattering in this sample was quite large relative to the ferromagnet spin wave scattering due to the spurious extra contributions from the coexistent antiferromagnetic phase that may indeed contain almost half the atoms.) The data of Fig. 1 also confirm that the spin wave energies reduce with increasing temperature as expected.

The spin waves measured at different q values show a quadratic dispersion as illustrated in Fig. 2 for the temperatures studied between 220 K ($0.93 T_c$) and 120 K ($0.51 T_c$) again reflecting conventional Heisenberg behavior. Lower temperatures could not be fully measured because of the above-mentioned restrictions on the energy range of the spectrometer. A small $q=0$ energy gap $\Delta \approx 0.1 \text{ meV}$ is evident and presumably originates from crystal field anisotropy. This is in contrast to the gapless behavior seen for the $x=0.33$ compound.⁵ It should be noted that the quadratic dispersion of Fig. 2, combined with the (0,0,0) origin for q ,

FIG. 3. Temperature dependence of the spin wave stiffness parameter D as a function of temperature. The solid line is the Brillouin function for $S=1.77$ that represents the magnetization.

FIG. 4. Scattering data at 220 K ($0.93 T_c$) for $q=0.08 \text{ \AA}^{-1}$ showing the central ($E=0$) mode intensity that is significantly smaller than that observed previously in an $x=0.33$ compound (see Ref. 5).

definitively confirms the existence of long wavelength *ferromagnetic* spin waves existing in a compound that also shows antiferromagnetic spin order.

Figure 3 shows the temperature dependence of the spin wave stiffness parameter D over the above temperature range. The stiffness exhibits significant renormalization with temperature again in contrast to the results for the $x=0.33$ sample.⁵ The figure also shows a curve of the Brillouin function for $S=1.77$ (effective Mn spin for this composition) normalized to $T_c=237$ K. This curve represents the temperature dependence of the Mn order parameter and also represents the approximate higher temperature dependence of D in a conventional ferromagnet. The extrapolated $T=0$ K value of the spin stiffness is 135 meV \AA^2 that gives a value of $D/T_c=0.57$ characteristic of an itinerant system.

The large $E=0$ parasitic scattering in this sample makes the determination problematical of the magnitude and q dependence of any central mode that appears as the spin waves merge into the elastic position on approach to T_c . Figure 4

shows the inelastic scattering (10 K data have been subtracted) at 220 K ($0.93 T_c$) and $q=0.08 \text{ \AA}^{-1}$. The solid lines are Gaussian fits to the expected spin waves and the central $E=0$ peak. Although within experimental uncertainty the central peak is not negligible, its intensity certainly does not exceed the spin waves by a factor of three as observed in the $x=0.33$ material at this same fraction of T_c ; nor is there much evidence of an exchange of spectral weight between the spin wave peaks and the central mode starting below $0.9 T_c$. It was suggested the large central mode is related to the formation of a magnetic polaron and is consequently found to be very sensitive to applied magnetic fields.⁶ The observed weakening or absence of these effects in other compositions would support this concept.

In summary our neutron results on $\text{La}_{0.53}\text{Ca}_{0.47}\text{MnO}_3$ show definitely coexisting phases of ferromagnetic and antiferromagnetic bulk spin ordering. The spin dynamics representative of the ferromagnetic phase were strongly characteristic of a conventional ferromagnet and did not show the anomalies found for the optimally doped $x=0.33$ compounds.⁵ While the antiferromagnetic spin waves could not be observed at the $q=0$ origin, their assumed presence did not destroy the ferromagnetic spin waves nor perturb them from conventional behavior.

Cold neutron triple-axis measurements have been used to investigate the nature of the long-wavelength spin dynamics in strongly doped $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ single crystals with $x=0.2$ and 0.3 . Both systems behave like isotropic ferromagnets at low T , with a gapless ($E_0 < 0.02$ meV) quadratic dispersion relation $E = E_0 + Dq^2$. The values of the spin-wave stiffness constant D are large ($D_{T=0} = 167$ meV \AA^2 for $x=0.2$ and $D_{T=0} = 176$ meV \AA^2 for $x=0.3$), which directly shows that the electron transfer energy for the d band is large. D exhibits a power law behavior as a function of temperature, and appears to collapse as $T \rightarrow T_C$. Nevertheless, an anomalously strong quasielastic central component develops and dominates the fluctuation spectrum as $T \rightarrow T_C$. Bragg scattering indicates that the magnetization near T_C exhibits power law behavior, with $\beta \approx 0.30$ for both systems, as expected for a three-dimensional ferromagnet. © 1998 American Institute of Physics. [S0021-8979(98)27311-7]

Since the recent discovery of unusually large magnetoresistive effects in perovskite manganites, the doped LaMnO_3 class of materials¹ has generated continued interest and has motivated experimental and theoretical work devoted to understanding of the origin of this colossal magnetoresistance (CMR) phenomenon. The large variation in the carrier mobility originates from an insulator-metal transition that is closely associated with the magnetic ordering. The on-site exchange interaction between the spins on the manganese ions is believed to be strong enough to completely polarize the (e_g) conduction electrons in the ground state, forming a "half-metallic" ferromagnet. However, hopping, and hence conduction, may only occur if the Mn core spins (formed by the d electrons in a t_{2g} orbital) on adjacent sites are parallel, which then directly couples ferromagnetic order with the electrical conductivity at elevated temperatures. This mechanism, known as the double exchange mechanism,² was first proposed in the 1950s, and has provided a good description of the evolution of the magnetic properties with band filling. However, in order to fully explain all the properties of the CMR materials, strong electron correlations,³ and/or a strong electron-lattice coupling⁴ in different polaronic approaches are invoked. This unique class of half-metallic ferromagnets provides an excellent opportunity to elucidate the influence of such correlations on the lattice and spin dynamics, which can best be probed by inelastic neutron scattering.

In the optimally doped regime with $x \sim 0.3$ it has been shown that the ground state spin dynamics is essentially that expected for a conventional metallic ferromagnet described by an isotropic Heisenberg model.⁵⁻⁷ For the Ca-doped system, however, results obtained on polycrystalline samples⁸ have indicated a possible coexistence of spin-wave excitations and spin diffusion in the ferromagnetic phase. In par-

ticular, it was suggested that it is this spin diffusion that drives the ferromagnetic phase transition rather than the thermal population of conventional spin waves. In the present publication we report diffraction and inelastic measurements of the spin dynamics in the metallic ferromagnets $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ and $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$.

The single crystals used in the present neutron scattering experiments were grown at the Steel and Alloys Institute in Moscow, using the floating zone method. The crystals weighed 2.25 and 4.25 g, respectively. The samples were oriented such that the $[100]$ and $[010]$ axes of the rhombohedral $R\bar{3}c$ cell lie in the scattering plane. The neutron scattering measurements have been carried out on the NG-5 (SPINS) cold neutron triple-axis spectrometer at the NIST research reactor. The (002) reflection of pyrolytic graphite (PG) was used as monochromator and analyzer for measuring the low-energy part of the spin-wave spectrum. We have used a flat analyzer with a fixed final energy $E_f = 3.7$ meV, a cold Be filter on the incident beam, and collimations $40' - S - 40' - 130'$ in sequence from the neutron guide to detector. This configuration offered an energy resolution of ~ 0.15 meV, together with good q resolution. Each sample was placed in a helium-filled aluminum cell in a displax refrigerator. The sample temperature ranged from 15 to 325 K for $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$, and from 30 to 375 K for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$, and was controlled to within 0.1° .

The crystal structure of both systems at room temperature and below is rhombohedral ($R\bar{3}c$), with $a_0 \approx b_0 \approx c_0 \approx 3.892$ \AA for $x=0.2$ and $a_0 \approx b_0 \approx c_0 \approx 3.884$ \AA for $x=0.3$.

Figure 1 shows the integrated intensity of the (100) Bragg reflection as a function of temperature for both samples. This reflection has a finite nuclear structure factor, and therefore the intensity in the paramagnetic phase is non-zero. The increase in intensity below T_C is due to magnetic scattering produced by the ferromagnetism of spins aligning

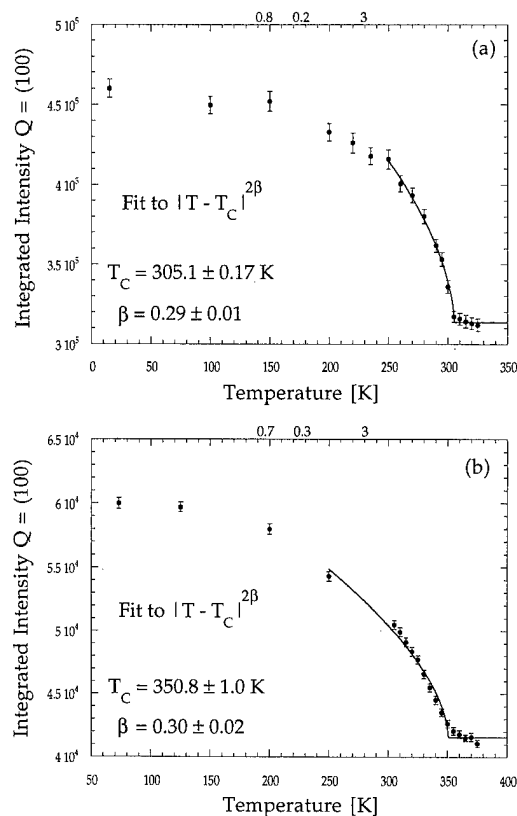

FIG. 1. Temperature dependence of the integrated intensity of the (100) Bragg peak for (a) $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ and (b) $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$. There is a nuclear contribution to this peak, and the additional temperature-dependent intensity originates from the onset of the ferromagnetic order at $T_C = 305$ K for the $x=0.2$ system, and $T_C = 350.8$ K for $x=0.3$. The solid curves are fits of the points near T_C to a power law.

on the manganese ions and yielding a magnetic structure factor. The solid curve is a fit of the points near T_C to a power law. The best fits give $T_C = 305.1$ K and a critical exponent $\beta = 0.29 \pm 0.01$ for $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$, and $T_C = 350.8$ K and $\beta = 0.30 \pm 0.02$ for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$. Both values of the critical exponent are slightly below, but rather close to, the well known three-dimensional Heisenberg ferromagnet model value of $\sim 1/3$.

We have investigated the spin dynamics in the (1,0,0) high-symmetry direction in both samples. The ground state spin dynamics for a half-metallic ferromagnet was not expected to differ much from the conventional picture of well defined spin waves, and we found that the long-wavelength magnetic excitations were in fact the usual spin waves, with a dispersion relation given by $E = E_0 + Dq^2$, where E_0 represents the spin-wave energy gap and the spin stiffness coefficient is directly related to the exchange interactions. The spin-wave gap E_0 was too small to be measured directly in energy scans at the zone center, but very high-resolution measurements on the NG-5 (SPINS) cold-neutron triple-axis spectrometer have allowed us to determine that $E_0 < 0.02$ meV for both systems, which demonstrates that these are "soft" isotropic ferromagnets. A previously reported value of $E_0 = 0.75$ meV for the $x=0.3$ system⁶ was obtained from an extrapolation of higher q data, not from direct high-resolution measurements as in the present case. The low-

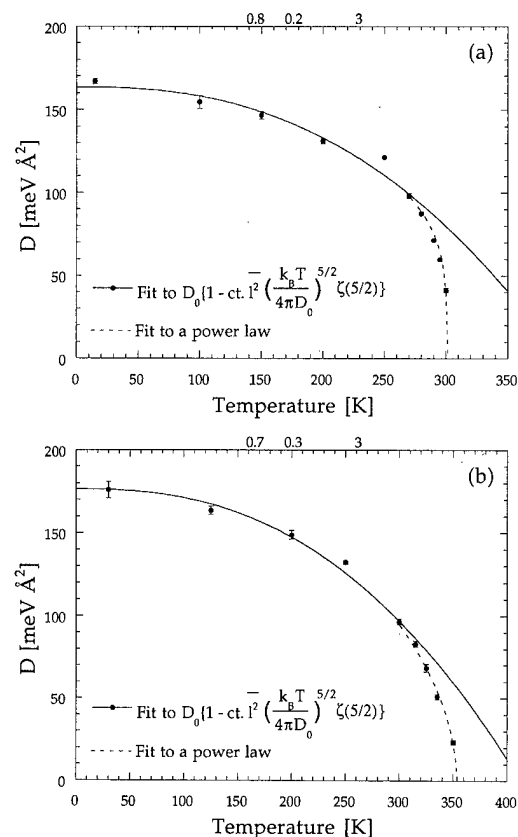

FIG. 2. Spin-wave stiffness coefficient D in $E = E_0 + Dq^2$ as a function of temperature for (a) $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ and (b) $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$. The solid curves are fits to Eq. (1). D appears to vanish at the ferromagnetic transition temperature, as expected for a conventional ferromagnet. The dashed curves are fits to a power law.

temperature values of the spin-wave stiffness constant D are large: $D_{T=0} = (166.8 \pm 1.51)$ meV \AA^2 for $x=0.2$ and $D_{T=0} = (176 \pm 5.00)$ meV \AA^2 for $x=0.3$, and give a ratio $D/k_B T_C \sim 6.34$ \AA^2 and 5.82 \AA^2 for the $x=0.2$ and 0.3 systems, respectively. Both values are quite large, as might be expected for an itinerant electron system.

Figure 2 plots the temperature dependence of the spin-wave stiffness D . The data have been analyzed in terms of two-spin-wave interactions in a Heisenberg ferromagnet within the Dyson formalism,¹⁰ which predicts that the dynamical interaction between the spin waves gives, to leading order, a temperature dependence:

$$D(T) = D_0 \left\{ 1 - \frac{v_0 \bar{l}^2 \pi}{S} \left(\frac{k_B T}{4\pi D_0} \right)^{5/2} \zeta\left(\frac{5}{2}\right) \right\}, \quad (1)$$

where v_0 is the volume of the unit cell, S is the average value of the manganese spin, and $\zeta(5/2)$ is the Riemann zeta integral. \bar{l}^2 is the moment defined by $\bar{l}^2 = S/3D \{ \sum J(\mathbf{r}) \}$ and which, compared to the square of the lattice parameter a^2 , gives information about the range of the exchange interaction. The solid curves in Fig. 2 are fits to Eq. (1), and are in good agreement with the experimental data for reduced temperatures $t = (T - T_C)/T_C$ up to $t_1 \approx -0.1$ for $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ and -0.14 for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$. The fitted values of \bar{l}^2 give $\sqrt{\bar{l}^2} = (3.92 \pm 1.04)a_0$ for $x=0.2$, and $\sqrt{\bar{l}^2} = (3.84 \pm 1.22)a_0$ for $x=0.3$, which indicates that the exchange interaction extends beyond nearest neighbors in both

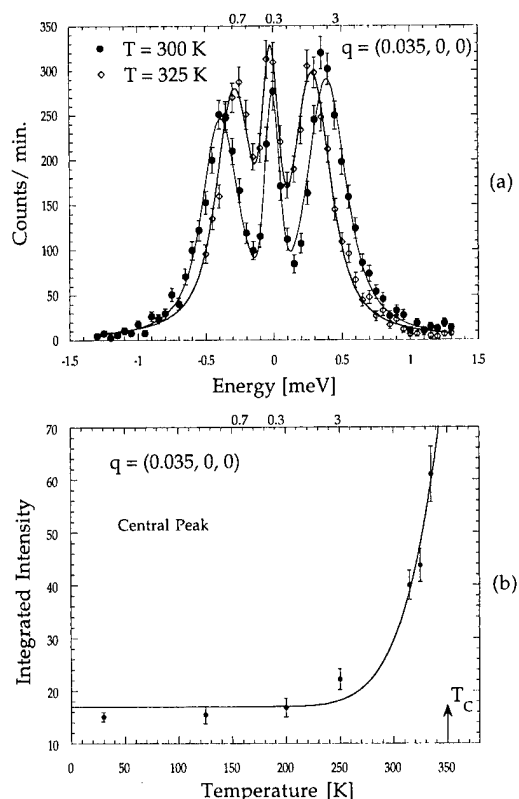

FIG. 3. (a) Constant- q magnetic inelastic spectra collected at 300 and 325 K and a reduced wave vector $q = (0, 0, 0.035)$ for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ ($T_C = 350.8$ K), and (b) temperature dependence of the integrated intensity of the quasielastic central component. The dominant effect is the development of a strong quasielastic component in the spectrum. Above T_C , all the scattering in this range of q is quasielastic.

systems. For $t > t_1$, the experimentally measured values of D depart from the $T^{5/2}$ dependence, having rather a power law behavior and appearing to collapse as $T \rightarrow T_C$. The dashed lines in Fig. 2 are fits to a power law $[1 - (T/T_C)]^{\nu' - \beta}$, where ν' is the critical exponent for a three-dimensional ferromagnet.

In the course of our measurements we have noticed that the central peak has a strong temperature dependence on approaching T_C , while typically the central peak originates from weak temperature-independent nuclear incoherent scattering. Figure 3(a) shows two magnetic inelastic spectra collected at 300 and 325 K, and reduced wave vector $q = 0.035$ away from the (100) reciprocal point in $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ ($T_C = 351$ K). A flat background of 4.9 counts plus an elastic incoherent nuclear peak of 110 counts, measured at 30 K, have been subtracted from these data. We can clearly see the development of the quasielastic component, comparable in intensity to the spin waves, and the temperature dependence of the strength of this scattering is

shown in Fig. 3(b) as a function of temperature. We observe a significant intensity starting at 250 K (~ 100 K below T_C), and the scattering peaks at T_C . At and above T_C all the scattering is quasielastic. For typical isotropic ferromagnets, such as Ni, Co, Fe, any quasielastic scattering below T_C is too weak and broad to be observed directly in the data, and can only be distinguished by the use of polarized neutron techniques. In Fig. 3(a) we can nevertheless see that the spectrum starts to be dominated by this quasielastic component at temperatures well below T_C . The appearance in the ferromagnetic phase of a quasielastic component was first observed on Ca-doped polycrystalline samples,⁸ and it has been suggested that it is associated with the localization of the e_g electrons on the $\text{Mn}^{3+}/\text{Mn}^{4+}$ lattice, and may be related to the formation of spin polarons in the system.⁹ We have observed a similar anomalous behavior of the central peak in the more lightly doped system $\text{La}_{0.85}\text{Sr}_{0.15}\text{MnO}_3$,¹¹ but for that doping we find that the central component becomes evident only much closer (~ 25 K) to the Curie temperature. It thus appears that the coexistence of spin-wave excitations and spin diffusion is a common characteristic for many perovskite manganites, and that it may be relevant for the giant magnetoresistance property of these systems. It is therefore important to pursue the study of this aspect with polarized neutron techniques, in order to determine the nature of the fluctuations involved in this new quasielastic component to the fluctuation spectrum.

The magnetic ordering of the Mn spins in polycrystalline $\text{Nd}_{0.62}\text{Ca}_{0.38}\text{MnO}_3$ has been investigated by means of neutron diffraction and ac magnetic susceptibility measurements. Three peaks around 230, 90, and 40 K were observed in the temperature dependence of the in-phase component of the ac susceptibility, $\chi'(T)$. Neutron diffraction measurements show that the peak at 90 K is associated with the ordering of the Mn spins, and that at 40 K is due to the reorientation of the Mn spins. Both ferromagnetic and antiferromagnetic coupling between the Mn spins were observed. The spins order at $T_N \approx 130$ K, with a spin structure consisting of ferromagnetically coupled, tilted antiferromagnetic sheets. No evidence was found from the neutron diffraction data to indicate that the peak around 230 K in $\chi'(T)$ is of magnetic origin, which suggests that it is associated with charge ordering. © 1998 American Institute of Physics. [S0021-8979(98)27411-1]

The discovery of colossal magnetoresistance (CMR) in distorted rare-earth containing manganites has sparked renewed interest in this class of materials.^{1,2} CMR as large as ten thousand fold has been observed in many systems. This phenomenon is now known to arise from the occurrence of a ferromagnetic transition accompanied by a insulator-metal transition, in which the double exchange (DE) interaction involving charge and spin exchanges is the main mechanism believed to be operating.^{3,4} The ferromagnetic metallic state is achieved by partially substituting trivalent rare-earth ions with divalent alkaline-earth ions. So far, the La-based compounds have been intensely investigated, whereas fewer studies have concentrated on the Nd-based systems. In this article, we present studies made on a Ca-doped Nd-based compound using neutron diffraction and ac magnetic susceptibility measurements. Charge ordering, tilted antiferromagnetic ordering of the Mn spins, and spin reorientation were observed.

Polycrystalline sample was prepared by the standard solid-state reaction techniques. Detailed sample fabrication procedures can be found elsewhere.⁵ The sample fabricated was characterized by a complete structural analysis using neutron powder diffraction and Rietveld analysis.⁶ High-resolution neutron diffraction patterns taken at eight temperatures were collected on BT-1, the 32-detector powder diffractometer at the U.S. NIST Research Reactor. A conventional setup of Cu(311) monochromator, pyrolytic graphite (PG) filter, and collimations of 15'-20'-7' full width at half maximum (FWHM) acceptance was employed. The high-resolution diffraction patterns were analyzed using the

General Structure Analysis System (GSAS) program.⁷ The refinements were carried out assuming the symmetry of space group $Pbnm$. There are essentially no unexpected peaks present, showing that the sample is practically single phase. We estimated the impurity level to be less than 1%. Careful analysis of the occupancy factors shows that 38% of the Nd sites are occupied by Ca atoms, while the O sites are almost fully occupied. Hence a chemical formula of $\text{Nd}_{0.62}\text{Ca}_{0.38}\text{MnO}_3$ is obtained. The compound crystallizes into an orthorhombic phase, with a crystal structure that may be viewed as a stacking of $\text{MnO}_2-(\text{Nd}/\text{Ca})\text{O}$ layers ($a-b$ planes) along the c axis direction. Lattice constants that we obtained at $T = 180$ K are $a = 5.4041(2)$, $b = 5.4526(2)$, and $c = 7.6274(4)$ Å.

The ac susceptibility measurements were performed on a conventional susceptometer, with which both the in-phase component χ' and the out-of-phase component χ'' can be measured. The temperature dependence of the ac susceptibility data were collected using a driving field of frequency 100 Hz and rms strength 1 Oe. Shown in Fig. 1 is the variation of χ' with temperature. Three peaks are seen over the temperature range studied. Using an expanded y scale, shown as an inset of Fig. 1, a small but definitive peak is clearly revealed around 230 K. This peak is *not* of magnetic origin (see below), and we believe it originates from charge ordering.⁸ The main feature seen in Fig. 1 is of course the huge but broad peak around 90 K. This peak is associated with the ordering of the Mn spins (see below), and it has an antiferromagnetic character as a cusp is present. At 40 K another peak is clearly seen in $\chi'(T)$, which is due to the change of the moment direction of the Mn spins (see below). This behavior is much

^{a)}Electronic mail: whli@joule.phy.ncu.edu.tw

FIG. 1. Temperature dependence of χ' measured using a driving field of frequency 100 Hz and rms strength 1 Oe. Three definite peaks at 230, 90, and 40 K are clearly seen.

reduced as a dc field is applied. No ac losses were detected, as essentially zero values were obtained for χ'' at all temperatures studied.

Neutron magnetic diffraction was performed also at the NIST Research Reactor. Data were collected on the BT-9 triple-axis spectrometer operated in double-axis mode, using a conventional setup with PG monochromator and filter. Neutrons of wavelength $\lambda = 2.351$ Å and angular collimations of 40'-48'-48' FWHM acceptance were used. A pumped ^4He cryostat was used to cool the sample. Diffraction patterns covering a range in scattering angle 2θ from 10° to 65° were taken at several temperatures ranging from 1.8 to 325 K. No structural changes were observed over the temperature range studied. Detectable nuclear peaks appear at 2θ greater than 30° , while the main magnetic peaks occur below 20° . Figure 2 shows the low scattering-angle portions of the diffraction patterns collected at four temperatures. At 160 K, which is above the temperature at which the most pronounced peak in $\chi'(T)$ appears, only background intensities are present in this 2θ range. At lower temperatures, several new peaks develop, while the background intensities become lower as the magnetic scattering evolve into Bragg peaks.

FIG. 2. Portions of the diffraction patterns taken at four temperatures. Only background intensities are present at 160 K. At lower temperatures, two magnetic peaks develop while the background intensities become lower. The intensities of these two peaks vary differently with temperature. The indices shown are based on the nuclear unit cell.

FIG. 3. Temperature dependence of the integrated intensities of the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}0\}$ reflections, showing a $T_N \approx 130$ K for the Mn spins. The two curves shown separate at 50 K. The inset shows the integrated intensity of the $\{202\} + \{022\}$ peak measured at high temperatures. No intensity variation is seen.

Based on the nuclear unit cell, the two peaks shown in Fig. 2 may be indexed as the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}0\}$ Bragg reflections, that originate from the ordering of the Mn spins. Clearly, the intensities of the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}0\}$ reflections vary differently with temperature, especially at temperatures below 15 K. The ratio between the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}0\}$ integrated intensities changes from being equal to 1.09 at 50 K, to 1.28 at 15 K, then to 1.40 at 1.7 K. These data indicate that the moment directions of the Mn spins vary with temperature. Besides the two peaks shown in Fig. 2, additional magnetic peaks that may be indexed as the $\{\frac{1}{2}10\} + \{1\frac{1}{2}0\}$, $\{\frac{1}{2}01\} + \{0\frac{3}{2}1\} + \{0\frac{1}{2}0\}$, and $\{\frac{1}{2}\frac{1}{2}1\}$ reflections were also observed (not shown).

The temperature dependence of the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}0\}$ integrated intensities are shown in Fig. 3. Both peaks begin to develop around 150 K. The ordering temperature of the Mn spins, as determined by the inflection point, is $T_N \approx 130$ K. Above 50 K, these two peaks follow essentially the same temperature-dependent curve, showing that the spin direction does not change over this temperature regime. Below 50 K, the intensity of the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ peaks increase faster than that of the $\{\frac{1}{2}\frac{1}{2}0\}$ peak, implying that the spin directions are changing with temperature. We note that a corresponding peak, which may be completely smeared by an applied dc field of 1 kOe, appears in the $\chi'(T)$ data. The intensity of the $\{\frac{1}{2}\frac{1}{2}0\}$ peak saturates at 15 K. This is the temperature at which the Mn moment is essentially saturated. However, the intensity of the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ peak continues to increase as the temperature decreases further. This intensity is still not saturated even at 1.7 K, the lowest temperature studied. If this further increase of the $\{\frac{1}{2}00\} + \{0\frac{1}{2}0\}$ intensity is due to the reorientation of the Mn spins, it must be accompanied by decreases of the intensities of other magnetic peaks. However, no such evidence was found. Instead, the intensity of the $\{\frac{1}{2}01\} + \{0\frac{3}{2}1\} + \{0\frac{1}{2}0\}$ peak was found to increase with reducing temperature as well. Another possible origin is the ordering of the Nd spins, and the observed data indeed may be explained quite well if one assumes the Nd spins are ordered with a simple antiferromagnetic arrangement. However, Nd spins usually order at quite low temperatures, lead-

FIG. 4. Schematic of the spin configuration in the a - b plane. The moment directions are arbitrarily chosen to be along the b axis for clarity.

ing us to propose that the moments on the Nd are induced by the ordered Mn moments. More data taken at lower temperatures are needed to make this argument conclusive.

At high temperatures, on the other hand, the intensity ratios did not vary significantly. Shown as an inset in Fig. 3 is the $\{202\} + \{022\}$ integrated intensity measured at high temperatures. No evidence was found to support the argument⁵ that the peak observed in $\chi'(T)$ around 230 K is due to a ferromagnetic transition induced by the Ca substitution.

Based on the data presented above, we propose the following magnetic structure and its variation with temperature for the Mn spins in $\text{Nd}_{0.62}\text{Ca}_{0.38}\text{MnO}_3$: The coupling of the Mn spins in the a - b plane is basically antiferromagnetic, while the interlayer coupling is ferromagnetic. Figure 4 shows the arrangement of the Mn spins in the a - b plane. It consists of antiferromagnetic chains along the b axis, with

the moment directions of every fourth chain tilted by a small angle with respect to that of other chains. The tilting is necessary to explain the appearance of the $\{\frac{1}{2}ll\}$ -type (l =integer) reflections that accompany the $\{\frac{1}{2}\frac{1}{2}l\}$ -type reflections, which we believe is caused by the Ca substitution. Our powder neutron data *cannot* resolve the a axis from the b axis due to their similarity. The specific moment directions in the a - b plane hence *cannot* be determined from our data. For clarity, in Fig. 4 we choose the moments to be basically along the b axis. Above 50 K the tilt angle is about 5° . Below 50 K this tilt angle increases with decreasing temperature, and reaches 15° as the Mn moments saturated at $T \approx 15$ K, with $\langle \mu_z \rangle = 2.07(3)\mu_B$.

Neutron scattering has been used to study the magnetic correlations in the double-layer manganite $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$, which exhibits colossal magnetoresistance in the vicinity of the ferromagnetic transition at $T_c = 112$ K. Over a large temperature range above T_c , there is evidence for two-dimensional magnetic correlations which peak in intensity at the transition. Although the in-plane correlations are predominantly ferromagnetic, a strong canting of spins in neighboring planes within the bilayers, at an angle that is dependent on both the temperature and magnetic field, is observed. There are indications of a crossover to three-dimensional critical scattering very close to T_c , but the nature of the phase transition has yet to be determined. © 1998 American Institute of Physics. [S0021-8979(98)45411-2]

I. INTRODUCTION

Colossal magnetoresistance can be strongly enhanced in systems with reduced dimensionality and so there has been considerable interest in the two-layer Ruddlesdon-Popper compounds, $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$, where x is the hole doping in the MnO_2 planes.¹⁻³ In zero field, these systems undergo a ferromagnetic phase transition at around 100 K with a concomitant metal-insulator transition. Although this transition temperature is much lower than in the three-dimensional Perovskite manganites, the reduced dimensionality leads to a significant extension of the temperature range over which magnetic correlations are important, and thereby allows a detailed examination of the link between local spin correlations and the resulting transport properties.

The origin of colossal magnetoresistance (CMR) was first explained by double-exchange interactions,⁴⁻⁶ but recently it has been proposed that electron-phonon interactions play an important role in enhancing the CMR.⁷ However, in the two-layer compounds, it was found that the influence of antiferromagnetic interactions competing with the ferromagnetic double exchange is of equal importance.^{3,8} This aspect was first considered nearly 40 years ago by de Gennes,⁶ but is only now being investigated further theoretically.⁹ As part of a general study to investigate the link between the magnetic and transport properties of naturally layered manganites, we have been measuring the magnetic correlations using neutron diffraction and spectroscopy.

II. EXPERIMENTAL RESULTS

A single crystal of the double-layer compound $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ with dimensions $2 \times 4 \times 6$ mm³ was grown using the floating-zone technique. Bulk measurements showed a ferromagnetic transition at $T_c \approx 112$ K in correspondence with the metal-insulator transition observed in resistivity measurements, both parallel and perpendicular to the MnO_2 planes. The lattice parameters are $a = 3.862$ Å and $c = 20.032$ Å at 125 K in agreement with earlier measurements for this composition.² More details on the preparation and characterization of this sample are given by Mitchell *et al.*² Neutron scattering experiments were performed on the triple-axis spectrometers BT2 and BT9 at the National Institute for Standards and Technology (NIST), Gaithersburg. Scans were taken in the $(0k0)$ scattering plane with incident neutron energies of 13.7 and 14.7 meV, without analyzing the energy of the scattered neutrons. A superconducting solenoid which provided vertical magnetic fields up to 7 T was employed in the measurements on BT9.

Diffuse scattering studies^{10,11} show clear evidence of spin correlations above T_c which have much longer correlation lengths within the MnO_2 planes than perpendicular to them. The two-dimensional character of these correlations is manifest in scattering in the form of rods perpendicular to the bilayer planes, i.e., parallel to $[00l]$ for all integer h in the scattering geometry used. Figure 1 shows the temperature dependence of this rod-scattering measured on BT2 at $\mathbf{Q} = [1, 0, 1.833]$. At this particular value of momentum transfer (for the given incident energy), the wavevector \mathbf{k}_f of the scattered neutrons is parallel to the c axis, leading to an optimal energy integration. The diffuse scattering is strongly

FIG. 1. Temperature dependence of the diffuse scattering measured at $Q = [1,0,1.833]$. A constant background, determined from a scan along $[h,0,1.833]$ at 4 K has been subtracted from the data. The solid line is a guide to the eye.

temperature dependent, becoming stronger in amplitude as the transition temperature $T_c = 112$ K is approached and peaking sharply at T_c . Below T_c , the scattering arises from inelastic spin wave excitations and therefore rapidly decreases with decreasing temperature.

Because of the large separation between different bilayers, we can expect the exchange interaction along the c axis to be small and the dispersion of the spin waves along this direction to be much weaker than in the plane. Recent spin wave measurements carried out on the cold triple-axis spectrometer SPINS at NIST indicated that the spin-wave energy at the zone boundary along the c direction is only ~ 0.5 meV, nearly two orders of magnitude smaller than the in-plane zone boundary energy. For our experiments ($T > 10$ K), the intensity is proportional to the magnon population, which is given by $n_q \sim k_B T / \hbar \omega_q$ when $k_B T \gg \hbar \omega_q$,¹² where ω_q is the spin wave energy along the c axis with momentum q . The observed diffuse scattering (Fig. 1) follows this linear dependence up to $T \sim 80$ K where the scattering increases more rapidly. This is evidence of a softening of the spin wave energies as T_c is approached.

The temperature and magnetic field dependence of the rods was studied by measuring both parallel and perpendicular to the rods at $[00l]$ and $[10l]$. Because of the large separation between different bilayers, the modulation of the diffuse scattering along the rods is determined by the spin correlations of Mn spins in neighboring layers within each bilayer, i.e., at $\mathbf{r}_i = \pm z\mathbf{c}$. The energy-integrated magnetic neutron scattering cross section for wavevector transfer \mathbf{Q} is then proportional to¹⁰

$$S(\mathbf{Q}) \approx S^2(1 + \langle \cos \theta \rangle \cos 4\pi z l). \quad (1)$$

Here θ is the in-plane cant angle of the two Mn spins. Since $z = 0.0965$ in the 40% compound,² the rod scattering due to ferromagnetic correlations ($\theta = 0$) would peak at $l = 0$ and fall to zero at $l = 2.59$. In-plane spin correlations produce a broadening of the rods along the $[h00]$ direction with the half-width equal to the inverse correlation length.

Figure 2 shows scans along $[0.95, 0, l]$, displaced from the $[1, 0, l]$ rod in order to avoid the nuclear Bragg peaks. For comparison, we have included data from Ref. 10 (upper part of Fig. 2). Clearly, the observed modulation along the rod is

FIG. 2. Diffuse scattering along the $Q = [0.95, 0, l]$ direction in a vertical magnetic field of 0 (circles), 0.5 (triangles), 1 (squares), and 2 T (diamonds). The solid lines are fits of Eq. (1) to the $T = 125$ K data with $\theta = 86.6^\circ$, 74.1° , and 53° , respectively. The upper part of the figure is taken from Osborn et al. (Ref. 10).

not very strong, even close to T_c , showing that $\langle \cos \theta \rangle \ll 1$. Either the magnetic correlations between the neighboring planes are extremely weak, or the spins are strongly canted with respect to each other. The first possibility seems unlikely since the nearest neighbor distance between the planes is nearly identical to the distance within the planes. The ferromagnetic in-plane correlation length is already 9.7 \AA at 125 K,¹⁰ which would give $\langle \cos \theta \rangle \approx 0.67$ for nearest neighbors, whereas the weak modulation is consistent with a value of $\langle \cos \theta \rangle = 0.06$. Such a difference would require the interaction between planes to be nearly two orders of magnitude weaker than within the planes. On the other hand, canting is predicted to occur when there is a competition between double exchange and superexchange interactions, as discussed below.

A magnetic field applied vertically along the b axis should lead to a decrease of the cant angle and to a stronger modulation, in agreement with our observation. From least-squares fits of Eq. (1), we determined an average in-plane cant angle of 86.6° at $T = 125$ K. This cant angle is reduced to 74.1° at $H = 1$ T and 53° at $H = 2$ T. Since, at this field strength, the diffuse scattering has become more inelastic and a substantial part of the scattering has been transferred to three-dimensional (3D) Bragg scattering, the diffuse signal has decreased strongly.

Reducing the temperature towards T_c leads again to an increase in the modulation so that the zero field and 0.5 T data at 112 K are very similar to the 1 and 2 T data, respectively, at 125 K. This similarity is seen in the lower part of Fig. 2, where the data measured at 112 K are shown together with the best fits obtained for the 125 K data.

FIG. 3. Diffuse magnetic and nuclear scattering along the $Q=[10l]$ direction at $T=120$ (circles), 116 (squares), 112 (stars), and 4 K (triangles). The solid line gives an indication of the Bragg peaks widths at $[10\pm 1]$.

Below 120 K, we observe an increase in the magnetic scattering around the $[10\pm 1]$ Bragg peaks along the $[10l]$ rod, which disappears again below T_C (Fig. 3). Since the in-plane correlations have no influence on the modulation along the rod, this scattering is due to the build-up of correlations between different bilayers. In other words, 3D correlations are developing as the transition is approached. However, because of the strength of the nuclear Bragg peaks, it has not been possible to derive out-of-plane correlation lengths.

III. DISCUSSION

Although measurements of spin wave dispersions, e.g., in LaMnO_3 ,¹³ have provided evidence of competing ferromagnetic and antiferromagnetic exchange interactions of the usual Heisenberg form, the observation of canted spin correlations is clear evidence of a competition between double exchange and superexchange. Nearest-neighbor Heisenberg exchange will only produce collinear ferro- or antiferromagnetic ordering. However, because the energy of double exchange interactions for a pair of spins depends on $\cos(\theta/2)$,⁵ rather than $\cos \theta$ as in the case of Heisenberg exchange, a minimum energy at $\theta \neq 0$ or π can result from a competition between the two.⁶ The large cant angles observed in our experiments imply that the double exchange and superexchange interactions are of the same order of magnitude in this compound.

Evidently, lowering the temperature towards T_C is equivalent to applying an in-plane magnetic field since both have the effect of reducing the cant angle. This is due to the growth of correlations between different bilayers, seen in Fig. 3, which produce an in-plane molecular field stabilizing ferromagnetic order and eventually lead to the 3D ordering at T_C . However, the nature of the transition is still uncertain. Earlier measurements of the in-plane correlation length indicate that it does not diverge at T_C ¹⁰ and so far no evidence of

a crossover to 3D scaling was found. From the strong anisotropy in the spin wave dispersion below T_C we estimate that the correlations between different bilayers are at least two orders of magnitude weaker than the correlations within the plane. Therefore, if there is a crossover to true 3D scaling, it would only occur within a narrow temperature range of about 1 K above T_C and could be smeared by sample inhomogeneity.

A nondivergent correlation length on the other hand would indicate that the transition is first order, although the evidence of spin wave softening below T_C (Fig. 1) and the absence of any hysteresis in this compound¹⁴ show that, if the transition is first order, it is only weakly so. In the case of the three-dimensional CMR perovskites, it was found that the transition in $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ is not a continuous second-order phase transition¹⁵ and it was argued that the nondivergence of the correlation length is related to the formation of magnetic polarons above T_C .¹⁶ However, it has not yet been established that this is a universal feature of CMR compounds, and from our present data, we cannot draw such a conclusion on the nature or the mechanism of the phase transition in the layered manganites.

The complex magnetic behavior and the role of dynamic structural fluctuations in $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ crystals

R. P. Sharma,^{a)} P. Fournier, R. L. Greene, and T. Venkatesan

Center for Superconductivity Research, Physics Department, University of Maryland, College Park, Maryland 20742

J. F. Mitchell and D. Miller

Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

The presence of dynamic structural distortions at the magnetic phase transitions in layered perovskite $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ crystals is found by ion channeling. Their amplitude is ~ 1.5 picometer between 70 and 150 K, twice as that expected due to the thermal vibrations and static changes seen by neutron diffraction. Over the range 150 to 320 K a total change of ~ 2.3 picometer is observed with discontinuities, which correlate well with the anomalous features seen in magnetic studies. In this material a small ferromagnetic component persists in the region 120 to 320 K, and it is fully paramagnetic above 320 K. © 1998 American Institute of Physics. [S0021-8979(98)45511-7]

Recent observation of colossal magnetoresistance effect¹⁻³ in doped perovskite-type manganites, like $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$, has generated great interest in these materials. A prominent feature of these materials is the observation of several orders of magnitude change in electrical resistance in response to the applied magnetic field at the ferromagnetic transition temperature (T_c). Efforts are being made to make them technologically viable, by improving their field sensitivity and magnetoresistance (MR) temperature dependence behavior. New materials are being searched. Even the perovskite-type structure has been modified recently into a layered-type structure by inserting a rock-salt-type $[(\text{La}, \text{Sr})_2\text{O}_2]$ block layer,⁴ for every n MnO_2 sheets, i.e., the compound $(\text{La}, \text{Sr})_{n+1}\text{Mn}_n\text{O}_{3n+1}$. In this system the double sheet, $n=2$ compound $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$, has been found to be a ferromagnetic metal below $T_c = 120$ K with large MR. It shows an unconventional magnetic response at temperatures well above T_c , and the transport properties are highly anisotropic.

There are different models which try to explain the transport properties of these manganites in terms of magnetic polarons, Zener double exchange, and Jahn-Teller distortions⁵ of the lattice. In the double exchange mechanism there is a simultaneous transfer of an electron from Mn^{3+} to O^{2-} and from O^{2-} to Mn^{4+} . In this mechanism, the travelling electrons tend to retain their spin orientation. If the orientation of the magnetic moments of the Mn^{3+} and Mn^{4+} ions is the same, there is an enhanced hopping probability. Hence any intrinsic alignment of the spins (e.g., onset of ferromagnetic order) or extrinsic alignment (e.g., application of an external magnetic field) could cause an increase in the conductivity. It has been also argued that the strength of the magnetic exchange interaction depends on the lattice distortions, (for example, in perovskite-type structure with orthorhombic distortions resulting from cooperative Jahn-Teller effect). A phase transition from a structurally distorted paramagnetic lattice with hopping-type conductivity to a ferromagnetic state will be accompanied by a dramatic reduction

in resistivity. However the magnitude of the observed effect cannot be totally accounted for by this picture.

The present investigations are performed on single crystals of the layered perovskite, double sheet, $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ crystals described above. Main stress is laid on the role of static and dynamic structural variations in this material. In order to remove any ambiguity, both the magnetization and ion channeling experiments have been made on the same specimen.

The ion channeling technique, which provides a direct real space probe of small atomic displacements from their regular lattice sites, even smaller than 1 picometer, is used to investigate the static and/or dynamic incoherent distortions in the above material. Ion channeling occurs when energetic ions, incident along a major crystallographic direction, are steered by the atomic rows and planes of a single crystal, through a series of correlated, gentle, small angle collisions.⁶ This phenomena causes one to two orders of magnitude reduction in a small impact parameter event such as Rutherford back scattering (RBS). The full width at half maximum (FWHM) of the channeling angular scan is directly related to any displacements (dynamic or static) of the atoms from their regular lattice sites. It is important to note that neutron and x-ray diffraction are relatively insensitive to local uncorrelated atomic displacements in the sample due to the fact that the diffraction data are analyzed within the constraints of a particular model based on the symmetry of the crystal space group. Random displacements from the ideal atom positions, whether static or thermal, contribute only to diffuse scattering, which is not included in the model.

The $\langle 100 \rangle$ crystals of $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ were melt grown in a flowing mixture of 20% O_2 and Ar as described elsewhere.⁷ These crystals were of dimensions $\sim 5 \text{ mm} \times 4 \text{ mm}$ and thickness about 1 mm. Both magnetization and channeling measurements were made on the same crystal and three sets of data were collected using three separate crystals. In these crystals the value of the resistivity ρ_{ab} at 300 K was found to be 120 m Ω cm which rose to about 3500 m Ω cm at $T \sim 133$ K, then dropped to ~ 60 m Ω cm at 108 K.

The dc magnetization measurements were carried out us-

^{a)}Electronic mail: rps@squid.umd.edu

FIG. 1. The magnetization m plotted as a function of temperature in 100 and 3000 Oe. The inset shows the low field measurement in an expanded scale to bring out small changes in magnetization.

ing a quantum design superconducting quantum interference device (SQUID) magnetometer both in a low field (100 Oe) and a high field (3 kOe). A transition to the ferromagnetic state was seen around 120 K which is in agreement with earlier measurements.⁴ In addition, a gradual rise in the magnetic moment is seen in the low field measurements (Fig. 1 inset) as the sample temperature is decreased from 300 to 120 K. The 77 K magnetic isotherms (Fig. 2) were measured with the field directions along a , b , and c , respectively, as defined in Fig. 2 ($a > b > c$). Saturation was reached at ~ 300 Oe when the magnetic field was along a and at about 800 Oe when it was along b as expected when considering static demagnetizing fields. The saturation value for $4\pi M(77\text{ K})$ is 4.4 kOe and is in good agreement with Ref. 4. However, when the field is along c , the magnetization does not saturate until $H \sim 20$ kOe. This is an indication of a large magnetocrystalline anisotropy with the hard axis along the c direction. Thus, the ab plane is the easy plane, as also indicated by Moritomo *et al.*⁴

The 140 K isotherms (Fig. 3) can be analyzed to provide evidence of a small ferromagnetic contribution. The high field magnetization gives a nonzero intercept at $H=0$, and the out-of-plane anisotropy is nonzero. There are no in plane shape effects; the hysteresis loops almost coincide when the magnetic field is applied along the a and b directions. For H applied along c , demagnetization and possible magnetocrystalline effects are seen. The 140 K measurements suggest that the geometry of the ferromagnetic regions is layered (thickness/area is very small) and that they lie in the ab

FIG. 2. The magnetization m vs H at 77 K with the magnetic field applied in the a , b , and c directions, respectively. The inset shows the data for a larger H scale in the c direction to indicate saturation of m .

FIG. 3. The magnetization m vs H at (a) 140, (b) 300, and 350 K. In (a) magnetic field is applied along a (\circ), along b (\bullet), and c (\times) directions. In (b) the field is applied along b direction.

plane. Even at 300 K the “ferromagnetic” response persists (Fig. 3), though with decreased magnitude. All signs of ferromagnetic response disappear at 350 K and only the paramagnetic response remains (Fig. 3), consistent with the T dependence shown in Fig. 1.

Ion channeling measurements have been carried out using a very well collimated beam (0.5 mm diameter and $<0.01^\circ$ divergence) of 1.5 MeV He ions obtained from a 1.7 MeV tandem pelletron accelerator. The sample was mounted with a thermally conducting paste on a precision four-axis goniometer having an angular resolution of 0.01° . The target holder was thermally insulated from the goniometer and could be cooled down to 35 K by a closed cycle refrigeration system. The effective pressure of condensable gases was reduced to a negligible level at the target surface by cryogenic shielding. The sample temperature was varied by a small 25 W heater, and could be maintained within ± 2 K at any desired temperature between 40 and 400 K.

The 1.5 MeV He⁺ beam was incident on the sample and the backscattered particles were detected in an annular surface barrier detector of 300 mm² active area with a 4-mm-diam central hole and mounted along the beam axis at a distance of 7 cm from the target. This arrangement gave RBS signals with good statistics at a nominal dose of incident He ions, thus minimizing the radiation damage effects. The channeling angular scans were made about the [001] axis of the crystal with the RBS gate which included the signals from La, Sr, and Mn. A minimum RBS yield of about 2% in these scans demonstrated a very high quality single crystal.

The FWHM of the channeling angular scans measured at different temperatures showed a clear enhanced variation of $\sim 12\%$ in FWHM in the region of T_c (70–150 K) and a few smaller variations in the wide region 150–320 K. Similar measurements were made on three specimens and a standard deviation of $<1\%$ was determined. The larger change is seen a little below T_c i.e., in the region of 90 K.

The FWHM of the channeling angular scans is directly related to small atomic displacements (static or dynamic), from their regular lattice sites, normal to the channeling direction. We extract the magnitude of the atomic displacement u , from the measured FWHM using the continuum

FIG. 4. The atomic displacement u as obtained from the measured FWHM of the channeling angular scans (●) and the calculated value of u (□) for normal thermal behavior vs T (30–160 K) in $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ crystals.

model⁶ for channeling, with corrections based upon the Monte Carlo computer simulation of Barrett⁷ and using average atomic numbers and lattice spacings. The results are shown in Figs. 4 and 5 as closed circles.

The decrease in thermal vibrational amplitude as a function of temperature is shown by the calculated values using the Debye relation in Figs. 4 and 5 (open squares). The measured variation in u is much larger than the expected thermal behavior. Between 70 and 150 K the total change was ~ 1.5 picometer, two times larger than the thermal change. This increase was not due to any abrupt change in thermal vibrations, but appears to be related to structural distortions (dynamic and/or static incoherent) in the specimen in the region of the transition to the ferromagnetic state.

There are a few smaller anomalies spread in the region 120–320 K. The change due to thermal vibrations in this region are of the order of 0.3 to 0.4 picometers. The deviation from normal thermal behavior is clearly seen and seems to be related with the para to ferromagnetic phase transition in certain regions in the material as indicated by low field magnetization measurements. It is clear that there are dynamic and/or static-incoherent structural changes associated with the phase transitions in the material.

As shown above, the $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ system is a complex inhomogeneous system, in which below 120 K, ferromagnetism dominates. Earlier in the spin resonance studies⁸ a multiline spectrum is seen at 115 K, which merges into a broad line below 80 K, indicating the possibility of different spin networks, i.e., a nonuniform ferromagnetic behavior. A

FIG. 5. Same as Fig. 4, but in the temperature region 150–360 K.

large MR is also seen in this region. In ion channeling, the maximum variation in the atomic displacement u is also spread in the region of 150–70 K. The transport properties, could be due to the double exchange mechanism and formation of polarons⁵ driven by Jahn–Teller distortion of the MnO_6 octahedra. Such distortions in terms of elongation along c and contraction in a axis in the region of 120 K are seen by neutron diffraction.⁹ This static change in a and c axes will not appreciably affect the FWHM of the channeling angular scans. Thus, there seems to be dynamic incoherent fluctuations in these octahedra, spread in the region 150–70 K before a long range magnetic order is reached, as seen by ion channeling (Fig. 4).

The small magnetic moment and corresponding transitions in the region 120–320 K could also arise from ferromagnetic intergrowths of $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ (LSMO) layers with different Sr/La concentration and a distribution of T_c . Although the ion channeling data cannot rule out the possible role of intergrowths, the magnitude of observed large variation in u between 150 and 320 K (Fig. 5) cannot be fully explained by such an intergrowth model. The channeling results represent the observed structural change from a thickness of ~ 3000 Å in the near surface region of the sample and ~ 2 intergrowths, each covering ~ 10 Å in this depth (seen in TEM). Thus it is unlikely that the intergrowths will affect the channeling to a measurable extent. It is possible that small locally correlated ferromagnetic (FM) spin networks, aligned parallel to the ab plane do exist in the system even at 300 K. In this double sheet material where every two magnetic layers (two dimensional networks of MnO_6 octahedra) are separated by an insulating layer, there seems to be two dimensional spin correlation. As the temperature is lowered below 300 K, the magnetic order increases slowly and incoherently (Fig. 1 inset). The existence of correlation between channeling anomalies and the magnetic behavior from 120 to 320 K could be intrinsic in origin. The possibility of two-dimensional magnetic order has been suggested by Potter *et al.*¹⁰ and the existence of antiferromagnetic clusters along with the ferromagnetic fluctuations is reported by Perring *et al.*¹¹ in the temperature region above 120 K in this material. The presence of antiferromagnetic clusters seems consistent with the above behavior. It hinders long range order in the c direction, thus supporting two-dimensional magnetic order. Below 120 K the fluctuations are much larger and are spread in a wider region since the whole system is passing through a nonuniform ferromagnetic state at the phase transition.

Lattice effects in ferromagnetic manganite perovskites

D. J. Singh

W. E. Pickett

Department of Physics, University of California, Davis, California 95616

Density functional calculations are used to investigate the relationships among lattice distortions, magnetic ordering, and electronic properties in manganite perovskites. Distortions open narrow pseudogaps at the middle of the majority e_g manifold. The effect on transport is very dependent on doping and falls off as divalent ions replace La in LaMnO_3 . Distortions in the ferromagnetic ordered colossal magnetoresistance regime are weakly coupled to electronic properties relative to pure LaMnO_3 . © 1998 American Institute of Physics. [S0021-8979(98)32111-8]

Understanding colossal magnetoresistance (CMR) in manganites depends on elucidating the metal-insulator transition at the Curie temperature, T_C . As noted early on,¹⁻³ there are strong couplings among doping level, lattice distortions, magnetic order and electronic properties. LaMnO_3 occurs in distorted Pnma orthorhombic or similar structures^{1,4} and is an A-type antiferromagnetic (AFM) insulator. The distortions, relative to cubic, are rotations of octahedra and Jahn-Teller (JT) effects that change Mn-O bond lengths (from 1.97 to 1.91, 1.96, and 2.18 Å). We use the term JT loosely for the nonrotational component. They are understood qualitatively via ion size and electron counting: La^{3+} and Mn^{3+} ionic radii yield a large misfit parameter, $\sqrt{2}(R_O + R_{\text{Mn}})/(R_O + R_{\text{La}})$, favoring rotations, while the high spin Mn^{3+} ion has a half occupied majority spin e_g orbital favoring JT distortions. Doping LaMnO_3 by substituting La^{3+} with divalent ions, the order becomes FM, lattice distortions are more purely rotational^{1,5,6} and CMR occurs. Several experimental and theoretical studies have suggested that lattice effects may be needed to understand CMR⁵⁻¹⁰ but, while clearly there are lattice anomalies at T_C , the extent of their direct influence on transport is still not established. Further, a CMR like effect has been discovered in a pyrochlore, $\text{Ti}_2\text{Mn}_2\text{O}_7$ that has neither lattice distortions nor nonintegral valence needed for a double exchange picture.¹¹⁻¹³

Local spin density approximation (LSDA) studies have been reported for the end-point compounds and some alloy compositions.¹⁴⁻²⁰ Besides verifying that known properties are reproduced, they have elucidated the electronic and magnetic structure. Well hybridized bands derived from majority spin Mn e_g states and O p states dominate the electronic structure near the Fermi energy, E_F in the metallic FM materials, while the minority spin channel is effectively insulating leading to half metallic properties.²⁰ This combined with the local moment behavior may be compatible with high resistivities in the spin disordered state above T_C even before consideration of lattice effects. The calculations also show strong couplings between lattice distortions, magnetic order and electronic properties at least in undoped LaMnO_3 . In particular, it is found that without lattice distortions LaMnO_3 would have a FM metallic ground state, and even if forced to be AFM, it would still be metallic.¹⁸ With the lattice distortion,

the ground state becomes A-type AFM, and is found insulating in agreement with experiment. The present article reports further calculations aimed at better understanding the role of lattice distortions in the CMR alloys $\text{La}_{1-x}\text{D}_x\text{MnO}_3$ near $x = 1/3$.

We used the linearized augmented planewave (LAPW) method²¹ as in our previous work.¹⁸ Calculations were done for 20 atom Pnma and 5 atom perovskite cells with well converged basis sets and zone samplings. Lattice parameters were fixed in relaxations since effects of homogeneous strains produced by anomalies measured at T_C ^{8,9} will be small compared to the bond length and angle changes due to JT and rotational distortions. Pnma symmetry was enforced, so that lower symmetry structures cannot occur.

Undistorted AFM LaMnO_3 is unstable against distortion, and this changes the electronic structure from metallic to insulating. This distortion has both a strong JT component and a rotation that changes the Mn-O-Mn bond angles from 180° to $\approx 160^\circ$. However, the CMR compositions are FM, and the question of the extent to which lattice distortion affects the electronic properties remains. A structural relaxation was performed for FM LaMnO_3 within the Pnma unit cell. The $x = 1/3$ composition range was studied with virtual crystal approximation calculations for $\text{La}_{2/3}\text{Ba}_{1/3}\text{MnO}_3$. These were for a structure approximating that of $\text{La}_{0.65}\text{Ca}_{0.35}\text{MnO}_3$ as determined by Dai *et al.*⁵ This had pseudocubic lattice parameters corresponding to the volume measured by Dai *et al.*⁵ and an average A-site cation charge $Z_{\text{VC}} = 56\frac{2}{3}$. The calculated electronic structure near and below E_F , should be representative of Sr or Ca substitution of La as well, since these are isovalent with Ba and the A-site cations are fully ionized. However, since Ba^{2+} ions are considerably larger than Ca^{2+} , the lattice will be under compressive strain which may alter the magnitude of lattice distortions in relaxations. The virtual crystal approach allows self-consistent treatment of the change in charge density and carrier density. Scattering due to the random occupation of the A site is not included. This has little effect on the broad bands characteristic of the FM majority spin channel, but localizes the minority spin carriers.²⁰ The relationship of virtual crystal and supercell calculations and reliability is discussed elsewhere.²⁰ Here we find that lattice distortions bring

TABLE I. Relaxed structure of FM Pnma LaMnO_3 . The pseudocubic lattice parameter is 3.936 Å.

	x	y	z
La	0.535	0.250	0.007
Mn	0.000	0.000	0.000
O1	0.013	0.750	0.071
O2	0.283	0.038	0.219

the minority spin band edge closer to E_F , further increasing the tendency towards minority spin localization, and as such transport is discussed in terms of the majority spin carriers only.

Relaxing Pnma FM LaMnO_3 a large rotational instability is found with final Mn–O–Mn bond angles of 165° , but the structure, as given in Table I, has almost no JT component. The Mn–O distances are all between 2.00, and 2.01 Å. The JT distortion occurs for AFM but not for FM order! This is another indication of large magnetostructural coupling in LaMnO_3 ; other evidence is the quite different crystal structures of FM and AFM modifications of LaMnO_3 ,⁴ the fact that magnetic order changes from FM to A-type AFM as the lattice is distorted,¹⁸ and that the structure changes from strongly orthorhombic in LaMnO_3 to more nearly cubic around the AFM to FM transition when doped with divalent A-site cations.¹

The electronic density of states (DOS) of undistorted cubic FM LaMnO_3 is shown in Fig. 1. The spin magnetization is $3.61 \mu_B$ per formula unit. The majority spin and minority spin DOS at E_F , $N(E_F)$ are comparable, and conduction in both spin channels is expected. Since we are interested in the CMR materials, where the minority carriers are localized, we focus on the majority channel. Calculations in the perovskite structure yield $N_\uparrow(E_F) = 0.45 \text{ eV}^{-1}$ and majority spin Fermi velocity, $v_{F\uparrow x} = 4.2 \times 10^7 \text{ cm/s}$. In Fig. 2, we show the DOS of FM LaMnO_3 in the relaxed structure. New gaps are opened between the hybridized t_{2g} and e_g manifolds in both the majority and minority channels, reflecting band narrowing due to less favorable hopping when the Mn–O–Mn bonds are bent. The distortion empties the minority states and thereby increases the magnetization to $4.00 \mu_B$ and lowers the energy by 0.24 eV, both on a per formula unit basis. Besides making FM LaMnO_3 essentially

FIG. 1. DOS of FM LaMnO_3 in the cubic perovskite structure. Majority spin is shown as positive and minority spin as negative. $E_F = 0$.FIG. 2. DOS of FM LaMnO_3 in the relaxed Pnma structure. The dotted line is the O contribution as defined by the weight inside the O LAPW spheres. The DOS is on a per formula unit.

half metallic, the distortion strongly reduces the majority spin conductivity. $N_\uparrow(E_F)$ becomes 0.21 eV^{-1} , while $v_{F\uparrow x} = 2.2 \times 10^7 \text{ cm/s}$ (although the symmetry is orthorhombic there is very little anisotropy in $v_{F\uparrow}$). If changes in scattering rate due to the distortion are neglected, as may be reasonable, an eightfold reduction in majority spin conductivity, σ due to the lattice distortion results within kinetic transport theory, where $\sigma \propto N(E_F)v_F^2$. This strong suppression of the conductivity with the lattice distortion is due to a pseudogap that opens in the majority channel at E_F . This occurs at the center of the roughly 3 eV wide e_g (hybridized with O $p\sigma$) derived manifold.

The DOS for virtual crystal $(\text{La}_{2/3}\text{Ba}_{1/3})\text{MnO}_3$ with the undistorted cubic perovskite structure shows near half metallic behavior with a smooth featureless majority spin component around E_F . The spin magnetization is $3.40 \mu_B$, with majority spin $N_\uparrow(E_F) = 0.53 \text{ eV}^{-1}$ and $v_{F\uparrow x} = 4.2 \times 10^7 \text{ cm/s}$. These values are similar to those obtained for perovskite structure FM LaMnO_3 .

Dai *et al.*⁵ reported neutron refinements of lattice parameters and some bond lengths and angles for FM Pnma $\text{La}_{0.65}\text{Ca}_{0.35}\text{MnO}_3$ at 300 and 40 K. The lattice parameters are very nearly pseudocubic (to about 0.2%), and the Mn–O bond lengths are all equal (to within 0.004 Å) showing a rotational component but no JT component to the distortion. The Mn–O–Mn bond angles are $160^\circ \pm 1^\circ$. We performed virtual crystal calculations using a Pnma structure derived from this one by making all bond lengths and Mn–O–Mn bond angles equal. The DOS is shown in Fig. 3. As in FM LaMnO_3 the distortion brings the minority spin band edge closer to E_F . The spin magnetization increases to $3.56 \mu_B$. Like undoped LaMnO_3 , a pseudogap opens at the center of the majority spin e_g manifold. At $x = 1/3$, the majority e_g manifold is far from half full, so the pseudogap is not near E_F . Rather, $N_\uparrow(E_F) = 0.68 \text{ eV}^{-1}$: somewhat larger than for the cubic structure. The velocity, $v_{F\uparrow x} = 3.1 \times 10^7 \text{ cm/s}$, is nearly isotropic and is reduced relative to cubic. The net result is that the distorted structure has a value $N_\uparrow(E_F)v_{F\uparrow x}^2$ that is reduced to 70% of the undistorted value, showing a relatively small effect from lattice distortions on the conductivity, particularly considering the large distortion that occurs. Thus there are couplings of lattice distortions and magnetic order to electronic properties in CMR alloys near

FIG. 3. DOS of virtual crystal $(\text{La}_{2/3}\text{Ba}_{1/3})\text{MnO}_3$ in the Pnma structure. Note the shift of the Fermi level in the majority bands compared to Fig. 2.

$x=1/3$, but these are weak, compared to those in pure LaMnO_3 . This is due to the narrowness of the e_g pseudogap that opens as the octahedra rotate in these materials. The calculations address the effects of static lattice distortions in fully ordered FM phases. They imply that the electron lattice coupling decreases strongly as LaMnO_3 is hole doped, a trend that is consistent with the high conductivities observed in some samples at low temperature. On the other hand, they do not address the metal insulator transition at T_C , which occurs simultaneously with a change in magnetic order. Observations of anomalies in Debye–Waller factors and lattice parameters near T_C imply significant coupling to the lattice. It has been observed by several authors that the properties above T_C are consistent with a polaronic state with strong charge carrier lattice interactions. Combined with the present results it would seem then that electron lattice interactions are stronger in the spin disordered paramagnetic state than the FM state. Previous calculations have shown that these local moment alloys are effectively half metallic when ordered and it is conjectured that this character persists locally for disordered states (strong Hund's rule). Carriers on Mn ions with moments rotated with respect to neighbors will be substantially localized and thus less strongly hybridized with O, as hopping is suppressed. These carriers occupy the JT active e_g orbital. This could lead to a local JT distortion,

providing a mechanism for strongly enhanced electron lattice interaction as spin disorder increases. This picture, related to that of Millis and co-workers,⁷ is consistent with a good metallic ground state, rapid onset of resistivity at T_C and a highly resistive paramagnetic state.

Isotope effect and T_c in manganites and high T_c oxides

Vladimir Z. Kresin

Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

Stuart A. Wolf

Naval Research Laboratory, Washington, DC 20375

Oxygen isotope effect in manganites (cuprates) is caused by the dynamic Jahn–Teller effect on the bridging oxygen ion (e.g., the ion between Mn^{3+} and Mn^{4+} in manganites). This effect leads also to the vibronic reduction and effective decrease of the ferromagnetic transition temperature.

© 1998 American Institute of Physics. [S0021-8979(98)32211-2]

I. INTRODUCTION

The oxides, cuprates, and manganites have attracted a lot of attention. The cuprates display a remarkable property, high-temperature superconductivity,¹ whereas the manganites are characterized by a number of unusual properties, inducing a very large magnetoresistance in the vicinity of the ferromagnetic transition.^{2–6} Needless to say that it is of definite interest to carry out the comparison of these two classes of materials. The nonadiabatic isotope effect in the cuprates was described by us in Ref. 7. As is shown in this article, one can also explain a large oxygen isotope effect observed in Ref. 5. It turns out that a similar scenario based on the dynamic Jahn–Teller (JT) effect determines the dependence of the transition temperature on oxygen substitution ($\text{O}^{16} \rightarrow \text{O}^{18}$) for the manganites. As is known, the transition to the ferromagnetic state (at $T = T_c$) has been described by the double exchange picture.^{8–10}

Both types of oxides have a similar structure. In both cases the doping plays a key role. In addition, one can observe the oxygen isotope effect. The isotope coefficient is very large for manganites, although it is not small in the underdoped cuprates.

Cuprates as well as manganites contain the Jahn–Teller (JT) ions, e.g., Cu^{++} , Mn^{+++} . This common feature is very important and, along with hybridization with oxygen orbitals, leads to unusual, non-adiabatic dynamics for the oxygen motion. For both systems one can observe a double-well structure of the potential. Below we are going to focus on this property of the materials.

II. MANGANESE OXIDES

Oxygen isotope substitution ($\text{O}^{16} \rightarrow \text{O}^{18}$) leads to a large effect on T_c . According to Ref. 5, the isotope coefficient $\alpha(T_c \propto M^{-\alpha})$ is equal to 0.85 for $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_{3+y}$ and 0.70 for $\text{La}_{0.9}\text{Ca}_{0.1}\text{MnO}_{3+y}$. In addition, the band structure analysis^{6,11} leads to a T_c about 2000 K which greatly exceeds the experimental value which is about of order of magnitude less (≈ 200 K).

These phenomena can be understood as a manifestation of the dynamic Jahn–Teller (JT) effect for oxygen. The key ingredient of our analysis is that the oxygen position is characterized by two close minima (double-well structure). This structure drastically affects the oxygen dynamics and is

caused by proximity to the crossing of two electronic terms (JT degeneracy). The JT splitting of the Mn ions, along with the manganese d -oxygen p hybridization³ leads to the JT behavior of the Mn–O–Mn unit. We focus on the vibrational motion of the oxygen ion which is the lightest member of the unit. Such a dynamic picture (two close minima) has been recently observed by a novel ion channeling technique in Ref. 12.

Our goal is to describe the charge transfer between two Mn ions; it is very important to take into consideration the peculiar oxygen dynamics. In this case the charge transfer is accompanied by transition between two electronic terms. It is very convenient to employ the method based on the diabatic representation (see, e.g., Ref. 13).

Because of the JT crossing, the total wave function $\psi(\mathbf{r}, \mathbf{R})$ (\mathbf{r} and \mathbf{R} are the electronic and nuclear coordinates, correspondingly) can be written in the form:

$$\psi(\mathbf{r}, \mathbf{R}) = C_\alpha \varphi_\alpha(\mathbf{r}, \mathbf{R}) \phi_\alpha(\mathbf{R}) + C_\beta \varphi_\beta(\mathbf{r}, \mathbf{R}) \phi_\beta(\mathbf{R}). \quad (1)$$

Here φ_i and ϕ_i ($i \equiv \alpha, \beta$) are the electronic and nuclear wave functions, corresponding to the α and β terms. Therefore, the total wave function is a superposition of two configurations α and β : $\alpha) \text{A}^+ \text{O}_\alpha \text{A}$, $\beta) \text{A} - \text{O}_\beta \text{A}^+$. In our case $\text{A} \equiv \text{Mn}^{3+}$, $\text{A}^+ \equiv \text{Mn}^{4+}$, $\text{O}_{\alpha(\beta)}$ is located near the left (right) minimum. In the diabatic representation the wave function $\Psi_\alpha = \varphi_\alpha \phi_\alpha$ coincides with the eigenfunction of the total electronic Hamiltonian $H_e = T_r + V(\mathbf{r}, \mathbf{R})$ in the region α and it is not an eigenfunction of H_e in the region β ; analogous behavior is true for ϕ_β (cf. Refs. 13 and 14; T_r is the electronic kinetic energy operator, V is the total potential energy). Substituting Eq. (1) into the stationary Schrödinger equation, one can evaluate the energy splitting ΔE between the symmetric and asymmetric terms. After a long, but straightforward calculation we obtain: $\Delta E = \int L(\mathbf{R}) \phi_\alpha(\mathbf{R}) \phi_\beta(\mathbf{R}) d\mathbf{R}$; here $L(\mathbf{R}) = \int \varphi_\alpha^*(\mathbf{r}, \mathbf{R}) H_e \varphi_\beta(\mathbf{r}, \mathbf{R}) d\mathbf{r}$ is the electronic factor. It is important to stress that this factor is an off-diagonal matrix element which is finite in the diabatic representation.¹³

The integrand in this factor differs from zero in the region a , a is the amplitude of the vibrations. The electronic factor has a scale l , l is the length of the bond. Since $l \gg a$, one can put $L(\mathbf{R}) \equiv L_0 \equiv L(\mathbf{R}_0)$ (\mathbf{R}_0 corresponds to the frozen lattice). We obtain: $\Delta E \equiv L_0 F$, where L_0 is the electronic factor, and

$$F = \int \phi_\alpha(\mathbf{R}) \phi_\beta(\mathbf{R}) d\mathbf{R} \quad (2)$$

is the Franck–Condon (FC) factor. It is essential that one can factorize the splitting into the electronic and FC terms.

The energy splitting corresponds to the time t for the jump between two Mn ions (see Ref. 8), that is to the period of oscillations between the configurations. Therefore, the splitting determines the critical temperature of the ferromagnetic ordering ($T_c \propto t^{-1}$, see Refs. 8, 11, 15), so that $T_c \propto \Delta E$. The electronic factor L [see Eqs. (2) and (3)] determines T_c for the usual double exchange model (see, e.g., Ref. 8). One can see that the JT dynamic instability of the O ion leads to an appearance of the additional FC factor. The inequality, $F < 1$, leads to a decrease in the value of T_c relative to the conventional result. Qualitatively, the charge transfer for the extra electron can be visualized as a multistep process; first the electron makes a transition from the Mn^{4+} site to the oxygen, then the oxygen transfers to another term, and this is finally followed by the transition of the electron to the other Mn ion. Therefore, the charge transfer contains an important additional step, namely, the oxygen transition between two terms. This additional step caused by the JT effect, leads to a drastic increase in the characteristic time for the jump between two Mn ions, and thus to a decrease in the strength of the ferromagnetic coupling, and, consequently, T_c . It is important, that the presence of the FC factor leads to the oxygen isotope effect (see below).

In order to estimate the FC factor, we are using harmonic oscillator wave functions. The factor is affected by the shift $\Delta\rho$ between the equilibrium positions. For simplicity, we consider a one-dimensional model. Simple calculation leads to the expression: $F = \exp(-\kappa^2)$; $\kappa = (\Delta\rho/2a)$, where $a^2 = (\hbar/m\Omega)$ is the amplitude of vibration. If we take the value $\kappa \approx 1.25$ –1.5 (this is consistent with the data¹²), we obtain $F \approx 0.18$ –0.2. If $L \approx 0.2$ (which alone would predict a T_{c0} between 1000 to 2000 K for La–Ca–Mn–O) (see Refs. 6 and 11), we obtain the value $T_c \approx 200$ –400 K, in an agreement with the experimental values. Note that the importance of the FC factor for the shift in the electronic excitation spectra for the intermediate valence systems was stressed in Ref. 16.

Let us now discuss the isotopic dependence observed in Ref. 5. This dependence is a direct consequence of the appearance of the FC factor [see Eq. (2)]. Indeed, this factor contains the nuclear wave functions and, therefore, depends on the nuclear mass M . The value of the isotope coefficient appears to be in good agreement with the data.⁵ Indeed, the isotope coefficient $\alpha(T_c \propto M^{-\alpha})$ is equal to $-(M/\Delta M) \times (\Delta T_c/T_c)$, where $\Delta M = M - M^*$ (we make the isotope substitution $M \rightarrow M^*$). Since $T_c \propto \Delta E \approx L_0 F$ (see above), we obtain $\alpha = -(M/\Delta M)(\Delta F/F)$. Based on the expression for the FC factor (see above), we obtain $\alpha = 0.5\kappa^2$. Using the value $\kappa \approx 1.25$ –1.5 for LaCaMnO (see above), we obtain the values in the range of 0.8–1.1, in an agreement with the value obtained in Ref. 5. Note that the values of κ and α depend on the sample and its preparation.

A more detailed quantitative evaluation using normal modes for the lattice configuration will be described else-

where. In this article, we describe the underlying physics and present the analysis that demonstrates that our model is in agreement with experimental data.

III. HIGH T_c OXIDES

Let us discuss the isotope effect in the cuprates. This problem was described by us in Ref. 7. As is known, the small value of the isotope coefficient α was considered as an argument against the phonon contribution to the pairing. However, it turns out that α strongly depends on the carrier concentration n and might exceed the BCS value $\alpha = 0.5$ (see, e.g., Refs. 17–19). It has been established that the minimum value of α corresponds to $T_c = T_{c,\max}$.

The oxygen dynamics in cuprates is also affected by presence of two minima. This has been observed in Ref. 12 by ion channeling and in Ref. 20 by x-ray (XANEX) measurements.

In order to describe the isotope effect in the cuprates, one can employ a method similar to that for the manganites. In accord with this, we are using the diabatic representation. In this case we focus on the charge redistribution between the reservoir (chains) and the CuO planes. Such redistribution requires an asymmetric positions of the minima (such a requirement is not needed for the manganites). In order to evaluate the carrier concentration, it is more convenient to use the quantum transition theory, that is to use a time-dependent picture. As in the case of manganites, the presence of the Franck–Condon factor is a key ingredient of our analysis. Its value strongly depends on the ionic mass and, therefore is affected by the isotope substitution. We obtain the following expression for the isotope coefficient (see Ref. 7):

$$\alpha_2 = \gamma \frac{n}{T_c} \frac{\partial T_c}{\partial n}, \quad (3)$$

where γ is a constant. Expression (3) allows us to compare directly with experimental data. Equation (3) contains the derivative $\partial T_c / \partial n$. Since T_c has a maximum at some value $n = n_{\max}$, the isotope coefficient α_2 is equal to zero if $T_c = T_{c,\max}$ (the small value of α actually observed is due to a small contribution from α_1). Therefore, the maximum value of T_c corresponds to a minimum in isotope coefficient.

Note that the dependence $n(M)$ is manifested not only in the isotopic dependence of the critical temperature. One can observe the isotope effect for the penetration depth,²¹ transport coefficients, etc., since they are affected by the value of the carrier concentration.

The cuprates contain different oxygen ions. If we are dealing with oxygen depletion from the chains, then the charge transfer is affected by nonadiabaticity of the apical oxygen. If we study the Pr substitution, then the charge transfer between the Pr ion and the CuO plane is modified by the JT dynamics of the in-plane oxygen (see Ref. 22).

IV. CONCLUSION

The isotopic dependence of the critical temperature for the transition to the superconducting (ferromagnetic) state is

caused by a nonadiabatic behavior of the oxygen ions. Oxygen dynamics for both types of oxides is characterized by presence of two close minima; their presence was observed experimentally in Refs. 12 and 20. The appearance of such double-well structure is due to the crossing of the electronic terms; this factor drastically affects the charge transfer, which is a key ingredient underlying many properties of the materials.

It is important to note that the double-well structure for the oxygen corresponds an unusual anharmonic picture. Indeed, according to such a picture the electronic and nuclear degrees of freedom are separated, but the potential for the nuclear motion is not harmonic. In our case we are dealing with a nonseparability of the motions, and the minima correspond to different terms.

It is essential to stress the difference between the nature of the phase transitions and isotopic dependencies for these two types of oxides. In both cases we are dealing with a dynamic Jahn–Teller instability of the oxygen ion. As for the superconducting transition in the cuprates, it is caused by a pairing interaction in the Cu–O plane, and the JT instability affects the doping level, that is, the carrier concentration in the plane n . The dependence $n(M)$ affects the value of the critical temperature. In the manganites the phase transition into the ferromagnetic state is due to the motion of the extra electron between Mn ions, and the JT dynamics of the O ion significantly affects the time scale, and therefore, the resulting value of T_c .

We study the competition between ferromagnetic double exchange (DE) and direct nearest-neighbor antiferromagnetic exchange J_{AF} in two-dimensional colossal magnetoresistance materials. Towards this end, a single site mean field theory is proposed which incorporates the hopping-mediated nature of the DE contribution. The canted state appears only under highly restricted conditions. Instead, in the regime where the antiferromagnetic and DE ferromagnetic interactions are of comparable scale (and in the classical limit), the system exhibits ferro- or antiferromagnetic order with incomplete saturation of the lattice or sublattice magnetization. We interpret these results as an indication that spin fluctuations remain strong even at low temperatures and discuss the associated experimental implications. © 1998 American Institute of Physics. [S0021-8979(98)45611-1]

The colossal magnetoresistance (CMR) manganese oxides have received considerable attention recently both theoretically and experimentally.¹ In the CMR regime, these materials exhibit ferromagnetism which is generally believed to result from a conduction electron-mediated double exchange (DE) mechanism.² There is, in addition, considerable evidence^{3,4} for antiferromagnetic exchange interactions of comparable scale, resulting from a superexchange mechanism. Thus, a full understanding of the magnetic order in the CMR materials requires a treatment of the competition between ferro- and antiferromagnetic interactions. The aim of the present article is to address this competition and by doing so, revisit earlier claims in the literature⁵ which suggest that spin canting may be the most natural means of accommodating these two opposing exchange interactions. Here in view of the considerable interest in the layered systems $\text{SrO}(\text{La}_{1-x}\text{Sr}_x\text{MnO}_3)_2$, we consider the two dimensional CMR compounds.

Our theoretical approach is based on a single site mean field theory which emphasizes the hopping-mediated nature of the DE contribution. In this way, we are led to consider the problem of off-diagonal (i.e., hopping) disorder associated with a single impurity atom in an otherwise uniform host material. This is to be contrasted with alternative approaches in the literature^{5,6} which implicitly introduce an exchange interaction to represent these DE effects. Our starting point is the standard Hamiltonian^{5,7} derived for the case of infinite Hund's rule coupling:

$$\mathcal{H} = -\frac{t_0}{2} \sum_{\langle i,j \rangle} \cos \frac{\theta_{ij}}{2} (c_i^\dagger c_j + c_j^\dagger c_i) + \frac{J_{AF}}{S^2} \sum_{\langle i,j \rangle} \mathbf{S}_i \mathbf{S}_j - \frac{H}{S} \sum_i S_i^z - \mu \sum_i c_i^\dagger c_i. \quad (1)$$

Here operator c_j annihilates a fermion on site j , \mathbf{S}_i represents a classical core (localized) spin ($S \gg 1$), J_{AF} is the nearest-neighbor antiferromagnetic exchange integral, H -external field, μ -chemical potential. Throughout this article, we use units in which the bare hopping t_0 , \hbar , κ_B , μ_B , and the lattice period are all equal to unity. In the first term of Eq. (1), we have omitted Berry phase effects which are insignificant for a single-site mean field treatment.

The Hamiltonian of Eq. (1) represents, at $T > 0$, a highly disordered electronic hopping problem, deriving from the random distribution of localized spins. In our mean field approach we focus on a central site characterized by hopping b to the surrounding sites. This site is embedded in a medium with average hopping t . These hopping matrix elements are the counterparts of the central spin and spin background encountered in standard mean field theories of magnetism and are associated with appropriate spin configurations. These parameters are indicated schematically in Fig. 1. Here $t \leq 1$, and $t \neq b$.⁸ To arrive at appropriate self-consistency conditions for b and t , we compute the change in thermodynamical potential Ω associated with the change in hopping matrix elements $t \rightarrow b$. Because of the locality of the perturbation this contribution to Ω can be evaluated exactly.⁹ For simplicity, we first present our results in the limit of small perturbations, $|t - b| \ll t$. To leading order in T/t

FIG. 1. Single-spin fluctuation in the ferromagnetic phase. The bold arrow represents average magnetization, and the dashed lines correspond to the hopping amplitude b , which differs from the background hopping value t (solid lines).

$$\delta\Omega_{\text{DE}}(b, t, T) \approx -2 \frac{t-b}{t} \int \epsilon f(\epsilon) \nu(\epsilon) d\epsilon \approx 2(t-b)|E_0|, \quad (2)$$

where E_0 is the kinetic energy of conduction electrons for $t=1$.

In the ferromagnetic case, which will be addressed first, this change in Ω is combined with terms arising from the superexchange and magnetic field components, so that the net contribution is

$$\delta\Omega_1 = \delta\Omega_{\text{DE}}(b_1, t, T) + 4J_{\text{AF}} \langle \cos \theta_{12} \rangle_2 - H \cos \alpha_1. \quad (3)$$

Here, θ_{12} is the angle formed by the spin \mathbf{S}_1 with a neighboring spin \mathbf{S}_2 and α_1 is the angle formed by the fluctuating spin \mathbf{S}_1 with the direction of average magnetization. We use the notation $\langle \dots \rangle_1$ to represent averaging over the Boltzmann probability distribution of spin \mathbf{S}_1 , $w_1 \propto \exp(-\delta\Omega_1/T)$. We find $\langle \cos \theta_{12} \rangle_2 = M \cos \alpha_1$, and

$$b_1^2 = \langle \cos^2(\theta_{12}/2) \rangle_2 = (1 + M \cos \alpha_1)/2, \quad (4)$$

$$t^2 = \langle b_1^2 \rangle_1 = (1 + M^2)/2.$$

The central mean field equation is given by $M = \langle \cos \alpha_1 \rangle_1$.

In the limit of small fluctuations of $\cos \alpha_1$ around its average value M , Eq. (2) can be used to deduce an effective exchange interaction for the ferromagnetic phase. For the 2D case this exchange constant is given by

$$J_{\text{eff}}(M) = J_{\text{DE}}(M) + J_{\text{AF}}, \quad (5)$$

$$J_{\text{DE}}(ME) \approx -\frac{1}{8} |E_0| \cdot \sqrt{\frac{2}{1+M^2}},$$

Here the DE contribution increases as M decreases, and is similar to that which is implicitly contained in alternative mean field schemes.^{6,10}

For moderately strong antiferromagnetic exchange interactions ($|E_0| + 2H < 8J_{\text{AF}} < \sqrt{2}|E_0| + 2H$), $J_{\text{eff}}(M)$ changes sign as M varies from 0 to 1. In Fig. 2 we plot the temperature dependence of the magnetization for this situation. Here the solid line corresponds to the fully self-consistent calculation, while the dashed line is obtained using Eq. (5). For comparison we plot (dotted line) the behavior obtained for a conventional Heisenberg magnet with the same T_c . The lack

FIG. 2. Magnetization vs temperature in the ferromagnetic phase at $H=0$, $x=0.4$, and $J_{\text{AF}}=0.06$. The solid, dashed, and dotted lines correspond to the 2D DE-superexchange magnet, effective exchange approximation, and usual Heisenberg ferromagnet (with the same value of T_c), respectively.

of saturation of the magnetization at low temperatures (in the classical limit) is a consequence of the competition between ferromagnetic and antiferromagnetic terms. As T decreases, the magnitude of single spin fluctuations also decreases. This leads to an increase of M , which in turn implies a decrease in $|J_{\text{eff}}|$ (and thereby a tendency to decrease M). Thus, through this self-adjustment of the effective exchange interaction (which never becomes large in comparison with T), the magnetization fails to saturate. Rather, the limiting value of the zero field, zero temperature magnetization is given by $M_0 = \{2[J_{\text{DE}}(1)/J_{\text{AF}}]^2 - 1\}^{1/2} < 1$. It can be seen from Fig. 2 that there are important differences, primarily at low temperatures, between the full calculation of M and that derived from the effective exchange approximation. This reflects the inadequacies of Eq. (2).

It should be noted that stability considerations indicate that other spin arrangements (such as the antiferromagnetic one) have higher energy at low T than the undersaturated ferromagnetic phase. However, the Néel phase is stabilized for $J_{\text{AF}} > 2^{-5/2}|E_0|$ in zero field, and, moreover, it always exhibits undersaturation of the sublattice magnetization.

DeGennes⁵ has argued that competition between DE and superexchange will result in spin canting. It should be stressed that his calculations were appropriate to a strongly anisotropic model (chosen to fit the known magnetic behavior of the undoped perovskite LaMnO_3). In this case the spins of entire lattice layers are locked together by a ferromagnetic exchange. Here we examine the stability of the canted state for an isotropic situation. For these purposes the nonperturbative expression for the change in thermodynamical potential $\delta\Omega_{\text{DE}}$ is required. Thus, other theoretical approaches^{6,10} based on Hartree-Fock-like approximation cannot address the canted phase. This phase is characterized by two ordered sublattices with equal sublattice magnetizations m , which form an angle 2γ between them. For the present Hamiltonian (within a mean field scheme), it can be seen that spin canting always requires the presence of non-zero magnetic field and low temperatures. The former is a consequence of the high degree of degeneracy of the zero field canted state. In zero field, the energy of the system

depends solely on the cosine of the angle which the spin S_1 (of sublattice I) forms with its nearest neighbors belonging to sublattice II. This energy does not change as the spin S_1 moves along any cone around the average direction of spins of sublattice II. Thus, on the average the spin S_1 will be aligned with sublattice II, rather than I. Thus, this degeneracy destabilizes the canted state. Moreover, these results are robust with respect to small perturbations (caused by anisotropy effects, quantum corrections, and small external fields) that may lift the degeneracy described above. Since this degeneracy is site local, its effects will be suppressed only when the energy scale of a perturbation per individual spin is comparable with that of the thermal motion of a single spin, that is, with the temperature T .

The canted phase is stable for $H > 0$, sufficiently strong antiferromagnetism ($8J_{AF} > |E_0| + H$), and at low temperatures. To characterize the canted state, one has to solve two coupled equations, one for the component of $\langle S_1 \rangle$ parallel to the magnetization of sublattice I,

$$-\sin 2\gamma \langle \sin \alpha_1 \cos \beta_1 \rangle_1 + \cos 2\gamma \langle \cos \alpha_1 \rangle_1 = m, \quad (6)$$

and another for the perpendicular component,

$$\cos 2\gamma \langle \sin \alpha_1 \cos \beta_1 \rangle_1 + \sin 2\gamma \langle \cos \alpha_1 \rangle_1 = 0, \quad (7)$$

where α_1 and β_1 are polar and azimuthal angles of the spin S_1 measured with respect to the coordinate system that has, as its polar axis, the average direction of the spins of sublattice II. We choose $\beta_1 = 0$ for the spin S_1 lying within the plane containing the two sublattice magnetizations.

In order to solve Eqs. (6) and (7), the full expression for $\delta\Omega_{DE}$ is needed. Following Ref. 9, it can be shown that

$$\delta\Omega_{DE}(b, t, T) = \int f(\epsilon) \xi(\epsilon) d\epsilon + \theta(b-t) \cdot [\varphi(z_0) - \varphi(-Dt)], \quad (8)$$

where the spectral shift function $\xi(\epsilon)$ is given by

$$\pi \text{ctg} \pi \xi(\epsilon) = -\frac{1}{\epsilon \nu(\epsilon)} \frac{b^2}{t^2 - b^2} - \frac{1}{\nu(\epsilon)} \text{V.P.} \int \frac{\nu(\eta) d\eta}{\epsilon - \eta}, \quad (9)$$

the bound state energy z_0 is the root of equation

$$1 + \frac{t^2 - b^2}{t^2} \left\{ -1 + z \int \frac{\nu(\eta) d\eta}{z - \eta} \right\} = 0, \quad (10)$$

$\nu(\epsilon)$ is the density of states, $\varphi(z) = -T \ln\{1 + \exp[(\mu - z)/T]\}$, and $f(z) = \{\exp[(z - \mu)/T] + 1\}^{-1}$. Equations (8)–(10) are valid for a square (cubic) lattice in any dimensionality D from 1 to 3; the energy integrations are performed over the entire conduction band, extending from $-Dt$ to Dt . In the canted state, Eqs. (3) and (4) have to be modified appropriately.¹¹

An analysis of these equations reveals an important feature of the canted state. As $T \rightarrow 0$, m approaches its proper saturation value $m=1$. This reflects the fact that at finite field, the canted state is associated with a nondegenerate energy minimum. Moreover, at temperature $T_1 \sim H$, the undersaturated ferromagnetic state undergoes a continuous phase transition into the low temperature canted state. This lends

support to the notion that undersaturation is characteristic of the generic low temperature regime.¹² Thus, the canted state does not appear in the $H=0$ phase diagram, which consists of antiferro- (low T , small x), ferro- (low T , larger x), and paramagnetic (high T) regions.

These calculations have made a number of predictions which can be tested experimentally. The layered materials $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$, with $x=0.4$, presumably lie either within the region where the system should display undersaturated ferromagnetic behavior at low T , or on the brink of this region, where thermal fluctuations should still be stronger than in a conventional magnet. Direct verification of the presence of undersaturation at low T should be possible via Rietveld measurements. The presently available results for the absolute value of magnetization in $x=0.4$ systems^{13,14} indicate that the low-temperature limiting value of the magnetization is lower than expected, but further experiments in a broader H, T range would be desirable.

It is natural to expect that the relative strength of the superexchange interaction is even higher in $x=0.3$ compounds, so that this compound may be suitable for observing canting under the proper field and temperature conditions: $T \lesssim H$, although experiments have not yet been performed in this regime. There have been no observations of the canted phase in the layered compounds to date, which is consistent with our results.

This work has benefitted from enlightening discussions that we had with many theorists and experimentalists. We are grateful to all of them, especially to A. G. Abanov, A. Auerbach, A. V. Chubukov, M. I. Kaganov, R. Osborn, R. Osgood, and A. E. Ruckenstein. The mechanism of carriers accompanied by spin-wave cloud and Jahn-Teller phononic cloud, called composite polaron, is proposed to explain the unusual transport and thermodynamic properties in perovskite manganites over all the temperature and magnetic field range. It is shown that the energy bandwidth of composite polarons is strongly renormalized with the increases of temperature and magnetic field, the bandwidth narrows with elevated temperature, while it broadens with increasing magnetic field. The resistivity of composite polarons increases with elevated temperature strongly, reaches a maximum near the Curie temperature T_C , and decreases with the increase of magnetic field. The specific heat of composite polarons also exhibits a maximum near T_C . These results agree with experiments in a broad temperature and magnetic field range, suggesting that composite polarons contribute to the unusual properties in manganites. © 1998 American Institute of Physics. [S0021-8979(98)45711-6]

I. INTRODUCTION

Huge resistance change under magnetic field found in ferromagnetic perovskite manganites has been under extensive theoretical and experimental studies in order to elucidate the mechanism of such a colossal change in resistance, and to explore its potential applications. The magnetic structure and the electronic states of $A_{1-x}R_x\text{MnO}_3$ (where $A=\text{La, Nd, Pr, ...}$ and $R=\text{Co, Sr, Pb, ...}$) were extensively studied since 1950's.¹ It is known that in manganites, three $d-t_{2g}$ electrons in Mn^{3+} and Mn^{4+} ions form localized core spins with $S=\frac{3}{2}$ via a strong intra-atomic Hund's coupling; the extra $d-e_g$ electron in Mn^{3+} , about 1.5 eV above the $d-t_{2g}$ level,² interacts with the core spins through strong Hund's coupling. The localized spins tend to align paralleled through the oxygen bridges among Mn^{3+} and Mn^{4+} ions and form ferromagnetic background.³ Electrons in the $d-e_g$ band hop between Mn ions as itinerant ones and are responsible for the electric conduction in these systems. This picture describes the essential process of the double exchange model.³⁻⁵

Several models⁶⁻¹⁰ have been proposed to explain the unusual transport properties observed in $A_{1-x}R_x\text{MnO}_3$ compounds. Early experiments⁶⁻⁸ had suggested that the anomalous magnetoresistance behavior could be understood in terms of the magnetic polaron mechanism. However, because of the Jahn-Teller distortion of MnO_6 octahedron,^{11,12} electrons moving together with the distorted crystalline field (dynamic Jahn-Teller distortion) will be damped or trapped by the distorted lattice potential and form phononic polaron.¹³ Recently many experiments¹⁴⁻¹⁶ confirm the exis-

tence of lattice distortion and the formation of polaron in doped lanthanum manganites. Millis *et al.*⁹ and Zang *et al.*¹⁰ suggested that the dynamic Jahn-Teller effect plays an important role in the doped manganites. However, their models only explained some of experimental facts. To fully understand the static and transport properties of manganites over all temperature and magnetic field range, further studies are still needed.

A moving electron in ferromagnetic (or antiferromagnetic) background disturbs its nearby local spin field and excites spin waves, so the moving electron at e_g level in lanthanum manganites is surrounded by spin-wave clouds and can form a magnetic polaron.¹⁷ On the other hand, in the presence of strong electron-lattice interaction, the magnetic polaron clouded by phonons can simultaneously form a kind of new quasiparticle, which we call the composite polaron (CP). In this article, we propose that the composite polaron is responsible for some unusual physical properties in manganites. The current work is different from our previous work¹⁸ where we did not discuss transport properties and specific heat. Approximation was made here in the low doping limit in order to calculate correlation functions.

II. FORMALISM OF COMPOSITE POLARONS

In $A_{1-x}B_x\text{MnO}_3$, it is believed that the essential interactions come from two parts, double exchange and Jahn-Teller lattice distortion. The double exchange interaction comes from the hopping of the e_g electrons between Mn^{3+} and Mn^{4+} ions via oxygen anion, which gives rise to the long-range ferromagnetic ordering among core spins. The dynamic Jahn-Teller electron-lattice coupling, originating from the degeneracy of e_g orbitals, is thought to play an

^{a)}Electronic mail: zou@isp.hfcas.ac.cn

important role for the transport properties⁹ and the magnetic properties.¹⁹ Considering these two interactions, the model Hamiltonian for the doped $R_{1-x}A_x\text{MnO}_3$ reads

$$H = \sum_{i\sigma} \epsilon_{d\sigma} d_{i\sigma}^\dagger d_{i\sigma} + t \sum_{\langle ij \rangle \sigma} d_{i\sigma}^\dagger d_{j\sigma} - J_H \sum_{i\mu\nu} \mathbf{S}_i \cdot d_{i\mu}^\dagger \sigma_{\mu\nu} d_{i\nu} - g\mu_B B \sum_i S_i^z + \alpha \hbar \omega \sum_i n_i [b_i^\dagger + b_i] + \sum_i \hbar \omega b_i^\dagger b_i, \quad (1)$$

where $d_{i\sigma}^\dagger$ creates an e_g electron at site \mathbf{R}_i with site energy ϵ_d and spin σ , t denotes the hopping integral of the e_g electrons from one site to its nearest-neighbor; b_i^\dagger creates a Jahn-Teller phonon at site \mathbf{R}_i with mode $\hbar\omega$, α represents the relative electron-phonon coupling constant. These parameters are chosen as $t \approx 1.8$, $J_H \approx 2.0$, and $\hbar\omega \approx 0.05$ eV, respectively; the relative electron-phonon interaction is about $\alpha \approx 1.5$.

Since the strong Hund's coupling between the conduction electron and the localized spin is confined to the same site, and since the strong Jahn-Teller coupling between the conduction electrons and the distorted lattice is extended only several lattice constant distance, the small polaron picture is more suitable for describing the motion of electrons in $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$. Therefore our treatment to Eq. (1) is in the framework of small polaron theory. The concept of the CP is supported by recent small-angle neutron scattering experiments by De Teresa *et al.*²⁰ After applying a unitary transformation²¹ to the model Hamiltonian Eq. (1) to eliminate the linear term of the phonon operators, $H' = e^{-S} H e^S$, where $S = \alpha \sum_i n_i [b_i^\dagger - b_i]$, one gets an effective Hamiltonian

$$H' = \sum_{i\sigma} \epsilon_{i\sigma} d_{i\sigma}^\dagger d_{i\sigma} + t \sum_{\langle ij \rangle \sigma} d_{i\sigma}^\dagger d_{j\sigma} \hat{X}_i^\dagger \hat{X}_j - J_H \sum_{i\mu\nu} \mathbf{S}_i \cdot d_{i\mu}^\dagger \sigma_{\mu\nu} d_{i\nu} \quad (2)$$

where $\epsilon_{d\sigma} = \epsilon_d - \mu - \sigma\mu_B B$, and $\hat{X}_{ia}^\dagger = \exp[\alpha(b_i - b_i^\dagger)]$. A constant term, $-\sum_{ij} \alpha n_i n_j$, is dropped off for simplicity.

The wave function of the composite polaron, $|\Phi\rangle$, can be constructed in terms of the basis functions, $|\phi_i(S_0^z)\rangle$,¹⁸

$$|\Phi\rangle = \sum_i a_i |\phi_i(S_0^z)\rangle \quad (3)$$

with

$$|\psi_i(S_0^z)\rangle = \sqrt{\frac{S+S_{0i}^z+1}{2S+1}} \left[d_{i\uparrow}^\dagger + \frac{d_{i\downarrow}^\dagger S_i^+}{S+S_{0i}^z+1} \right] |0\rangle_e,$$

where a_i^\dagger creates a CP and $|0\rangle_e$ denotes the fermion vacuum state. In the CP representation, the Hamiltonian Eq. (2) is rewritten

$$\tilde{H} = \sum_i \tilde{\epsilon}_0 a_i^\dagger a_i + \frac{t}{2S+1} \sum_{\langle ij \rangle} \left[\sqrt{(S+S_{0i}^z+1)(S+S_{0j}^z+1)} + \frac{1}{\sqrt{S+S_{0i}^z+1}} S_i^- S_j^+ \frac{1}{\sqrt{S+S_{0j}^z+1}} \right] X_i^\dagger X_j a_i^\dagger a_j. \quad (4)$$

In Eq. (4), the first term is diagonal, $\tilde{\epsilon}_0 = \epsilon_d - \alpha \hbar \omega - J_H S - 2S/(2S+1)(\mu_B B + g/2S \mu_B B)$, denoting the spin-dependent and the phonon-dependent site energy of the CP and describing the central position of energy band of the CP, which is almost not shifted by temperature and applied magnetic field; the second term, the nondiagonal part, describes the hopping process and the energy band of the CP, which contributes to the transport properties. After the thermal average over phononic states and spin configurations, the energy band of the CP can be obtained:

$$\epsilon_k = \tilde{\epsilon}_0 + \frac{zt\gamma(k)}{2S+1} e^{-\alpha(\langle n_B \rangle + 1/2)} \times \left[\langle \sqrt{(S+S_{0i}^z+1)(S+S_{0\delta}^z+1)} \rangle + \left\langle \frac{1}{\sqrt{S+S_{0i}^z+1}} S_i^- S_{i+\delta}^+ \frac{1}{\sqrt{S+S_{0i+\delta}^z+1}} \right\rangle \right]. \quad (5)$$

It is interesting to compare the above dispersion with the bare energy spectrum of conduction electrons, $zt\gamma(k)$. It is found that the energy band of the CP is renormalized by a phononic part depending only on temperature and a magnetic part depending both on temperature and magnetic field. The increases of electron-phonon interaction and temperature narrow the energy band of the CP, while the increase of magnetic field broadens it. It can be shown that when temperature varies from 50 to 250 K, the CP bandwidth in $\text{La}_{0.67}\text{Co}_{0.33}\text{MnO}_3$ decreases by about one order in magnitude.¹⁸ With the increase of temperature from $T < T_C$ to $T > T_C$, the spin-dependent correlation function exhibits a minimum near T_C , so the bandwidth of the CP has a minimum. Thus the CP energy band is controlled by both temperature and magnetic field, in agreement with the experimental observation.²²

III. TRANSPORT PROPERTIES OF COMPOSITE POLARONS

According to the preceding analysis, the CP formed in doped LaMnO_3 is a type of small polaron and its transport properties can be obtained from the small polaron theory. The direct-current conductivity is deduced from the Kubo formula²³ in terms of the nondiagonal transition process

$$\sigma = \frac{\beta}{6} \left(\frac{t}{2S+1} \right)^2 \sum_{ij\delta\delta'} \delta \cdot \delta' \int_{-\infty}^{\infty} dt \langle a_i^\dagger(t) a_{i+\delta}(t) a_{j+\delta'}^\dagger a_j \rangle \times \langle X_i^\dagger(t) X_{i+\delta}(t) X_{j+\delta'}^\dagger X_j \rangle F_{ij}(\delta, \delta', t). \quad (6)$$

Here $F_{ij}(t)$ is a spin-dependent correlation function. The conductivity is measured in the units of e^2/\hbar and it can be calculated so long as these correlation functions are known in the presence of magnetic field at temperature of T .

Assuming that the leading contribution of the CP to the direct-current conductivity comes from the self-correlation part, i.e., $j=i$, $\delta=\delta'$, to the zero-order approximation of the expansion of S matrix in the interaction representation, the correlation function for the CP becomes of the product of the occupied number of the CP in one site and the unoccupied

number in the nearest neighbor site, $n_i(1 - n_{i+\delta}) \approx c(1 - c)$, where c is the concentration of the CP per site. The thermal average of the Jahn–Teller phononic correlation function gives rise to $\exp\{-2\alpha^2(\langle n_B \rangle + 1/2)[1 - 2\cos(\omega t) + \cos(2\omega t)]\}$, where $\langle n_B \rangle$ is the thermal averaged occupation of the phonon. The spin-dependent correlation function in Eq. (5) is that of the double exchange ferromagnet and the expression of $F_{ij}(B, T)$ is rather complicated. Detailed calculation will be given in a further article.²⁴

Temperature dependence of the resistivity of the CP is obtained numerically and it agrees with the experiments well.^{6–8} The temperature and the field behavior of the CP could be understood as follows: at temperatures below the Curie temperature T_C , there exists both ferromagnetic long-range order and dynamic electron-phonon coupling, more and more spin waves and phonons are excited with the increase of temperature, the CP becomes more and more heavy and is trapped, so the electric resistivity of the CP increases. Above T_C , only the short-range magnetic order and the Jahn–Teller effect play roles, the hopping probability of the CP increases with the elevating temperature, so the resistance declines. The resistivity maximum in CMR compounds near T_C originates from the crossover of the magnetic contribution for the CP from the long-range order to the short-range order of double exchange ferromagnet.

The application of external magnetic field to system suppresses the spin excitation and reduces the effective mass of the CP, so the resistivity decreases with the increase of magnetic field. These behaviors agree with experiments very well.

One important result of the present model is that the magnetic scattering contribution to the resistivity comes from both the two-point spin-correlation function of the short-range ($T > T_C$) or the long range ($T < T_C$) magnetic fluctuations, and the four point spin correlation function¹² if high order approximation is adopted. Therefore the CP mechanism may be a more suitable description for the unusual properties of lanthanum manganites than either the magnetic polaron or the Jahn–Teller polaron mechanism.

IV. SPECIFIC HEAT OF COMPOSITE POLARONS

The thermodynamic properties of lanthanum manganites also can be deduced from the properties of the CP. The specific heat can be obtained from the total energy of the CP in the system,

$$C_v = \frac{\beta^2}{4} \sum_k \epsilon_k (\epsilon_k - \mu) Ch^{-2} [\beta(\epsilon_k - \mu)/2], \quad (7)$$

where the specific heat is in the units of k_B , ϵ_k denotes the energy band of the CP. Also we need the spin-dependent correlation function to calculate the specific heat of the CP. Since it is hard to obtain analytic results from such a complicated polaron energy band, the numerical result of the temperature dependence of the specific heat is obtained. It is

found that the specific heat of the CP increases gradually with the increasing of temperature, and exhibits a maximum near the Curie temperature. This maximum is related to the crossover of the leading contribution to the CP from the magnetic scattering character ($T < T_C$) to phononic scattering character ($T > T_C$). This behavior also agrees with recent experiments.²⁵

V. CONCLUSION

To summarize, a new kind of quasiparticle, the composite polaron, can form in the doped lanthanum manganites. The unusual transport and thermodynamic properties in manganites could be understood in the framework of the composite polaron theory.

Tunneling evidence of half-metallicity in epitaxial films of ferromagnetic perovskite manganites and ferrimagnetic magnetite

Direct evidence of half-metallic density of states is observed by scanning tunneling spectroscopy of ferromagnetic $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ and $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.3, 0.33$) epitaxial films which exhibit colossal magnetoresistance (CMR). At 77 K, well below the Curie temperatures, the normalized tunneling conductance $(dI/dV)/\langle I/V \rangle$ for all samples exhibits similar pronounced peak structures, consistent with the spin-split density of states spectra for the itinerant bands in the ferromagnetic state. The exchange energy splitting between the majority and minority spins, as well as an apparent energy gap near the Fermi level, show variations with the chemical composition and the temperature. For comparison, the tunneling spectrum of a half-metallic ferrimagnet Fe_3O_4 is also studied. The characteristic spin-split density of states spectrum is observed, and the similarities and differences of Fe_3O_4 compared with the perovskite manganites are discussed. © 1998 American Institute of Physics. [S0021-8979(98)45811-0]

Half-metallic ferromagnetic materials, characterized by the presence of an energy gap for one of the spin orientations at the Fermi level and continuous bands for the other, have been a subject of interest for more than a decade.¹⁻⁴ An important consequence of the half-metallicity is the complete spin polarization in the ferromagnetic state of these materials,^{1,2} giving rise to novel physical properties, such as very large magneto-optical Kerr effects⁵ in the Heusler alloys (e.g., PtMnSb).⁶ Recently, the intensively studied phenomenon of negative colossal magnetoresistance (CMR) in the perovskite manganites, $\text{Ln}_{1-x}\text{M}_x\text{MnO}_3$ (Ln: trivalent rare earth ions, M: divalent alkaline earth ions), has been attributed to the half-metallic characteristics of these materials based on electronic band structure calculations⁷ and on various supportive though indirect experiments.^{8,9} In this work, we provide temperature-dependent tunneling spectroscopy data as direct experimental evidence for the half-metallicity of various perovskite manganites. In addition, we compare these results with the first temperature-dependent tunneling spectroscopy data ever taken on a ferrimagnetic half-metal, Fe_3O_4 .¹⁰⁻¹² The similarities and differences in the spectral behavior of these half-metallic ferromagnets and ferrimagnets (HMF) are discussed.

The perovskite manganites studied in this work are 200-nm-thick epitaxial films of $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ and $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ grown on single crystalline LaAlO_3 substrates,¹³⁻¹⁶ and 150-nm-thick $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ on single crystalline SrTiO_3 substrates, using pulsed laser deposition.¹⁷ The Curie temperatures (T_C) for these samples are 260, 320, and 360 K, respectively. Details of the deposition procedure

and the characterizations of the structural and physical properties (including the electronic, electrical transport, magnetic, and optical properties) of the manganite epitaxial films have been reported elsewhere.¹³⁻¹⁷ The Fe_3O_4 sample is an epitaxial film grown on a (001)-oriented MgO substrate, also using the pulsed laser deposition technique.¹²

To investigate the HMF characteristics of these ferromagnetic films, we employ tunneling spectroscopy on these samples using a variable-temperature scanning tunneling microscope (STM). Tunneling spectroscopy is known to be a sensitive probe for studying the density of states of material,¹⁸ particularly if the tunneling is into a many-body system characterized by a renormalized quasiparticle dispersion.¹⁹ In this work, we study the tunneling spectroscopy of the magnetic epitaxial films by measuring the tunneling current as a function of the sample bias voltage. All measured spectra are highly reproducible, and the characteristics are essentially independent of the junction impedance, ranging from high impedance $\sim 100 \text{ M}\Omega$ to low impedance $\sim 1 \text{ M}\Omega$. We use paramagnetic Pt for the tunneling tip to prevent possible complications in revealing the magnetic properties of the samples.

The main panels of Figs. 1(a)–1(c) illustrate the differential conductance, $(dI/dV)/\langle I/V \rangle$, normalized with the standard formalism given in Ref. 18, as a function of the bias voltage (V) for $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ (LCMO), $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ (LSMO), and Fe_3O_4 films at $T=77 \text{ K}$, respectively. The insets depict the corresponding data taken at $T=300 \text{ K}$. Similar measurements have also been conducted on the $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ sample, and the results are qualitatively similar to those obtained on the $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ sample, although small quantitative differences exist. These quantitative variations are given in Table I.

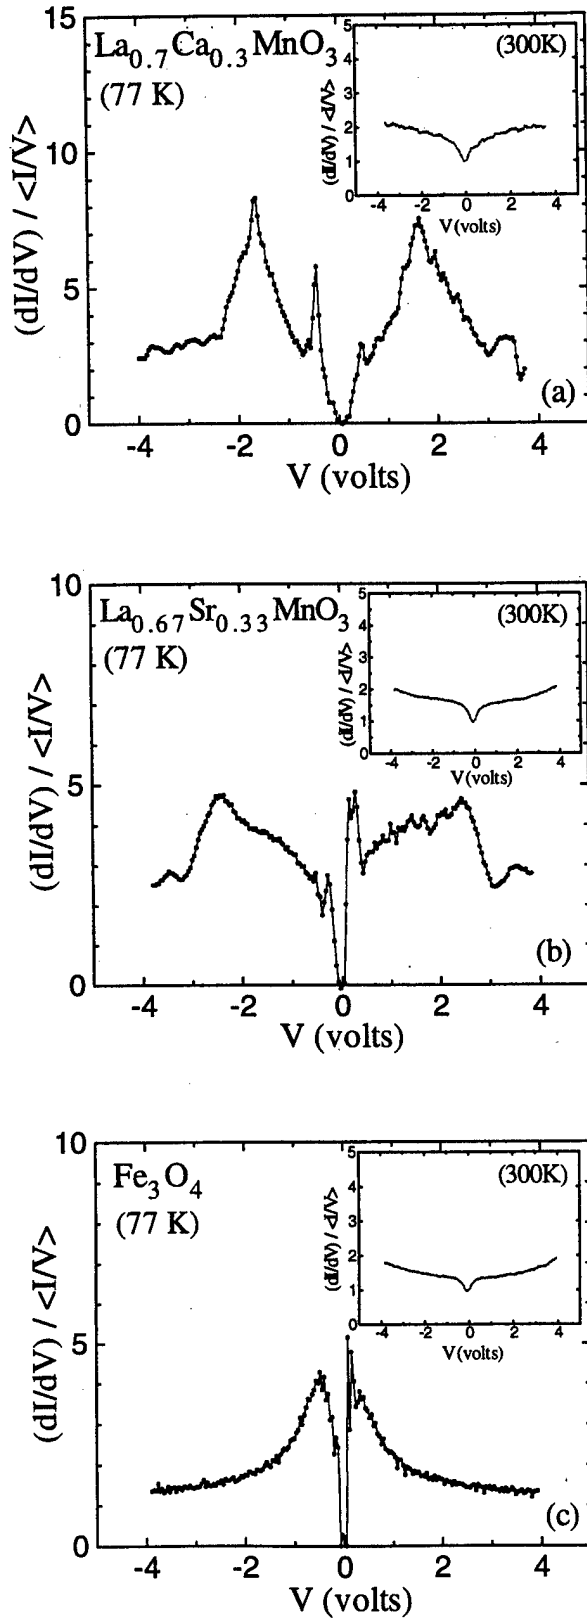

FIG. 1. The normalized differential conductance, $(dI/dV)/\langle I \rangle$, of (a) $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$, (b) $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$, and (c) Fe_3O_4 , as a function of the bias voltage V at $T=77$ K. The insets show the corresponding tunneling spectroscopy data at 300 K. The exchange energy splitting ΔE_{ex} and the energy gap ΔE_G values determined from the low-temperature data are given in Table I.

TABLE I. Summary of the tunneling spectroscopy measurements on the manganite and magnetite epitaxial films. The uncertainties in the energies come from spectral variations, and T_v is the Verwey temperature for Fe_3O_4 .

Material	T_C [K]	ΔE_{ex} [eV]	ΔE_G [eV]
$\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$	260	3.3 ± 0.2	0.9 ± 0.1
$\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$	320	4.0 ± 0.2	0.7 ± 0.1
$\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$	360	5.0 ± 0.2	0.6 ± 0.1
Fe_3O_4	850 ($T_v = 120$ K)	0.8 ± 0.2	0.2 ± 0.1

Several important features of the data are noteworthy. First, two large peaks, which correspond to the density of states of the majority and minority carriers energetically separated by the on-site exchange energy, are clearly visible in each sample at 77 K. These features disappear at room temperature. Second, near zero bias voltage, the normalized differential conductivity appears to be zero for each sample at 77 K, suggesting the existence of a small energy gap ΔE_G near the Fermi level, attributable to either a density-of-states gap in the minority band or a mobility gap in the majority band.⁴ Furthermore, ΔE_G is the largest in LCMO and the smallest in Fe_3O_4 . Third, in the case of perovskite manganites, the exchange energy splitting ΔE_{ex} for the same alkaline earth doping level $x=0.3$ is larger in $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ ($\Delta E_{\text{ex}} = 4.0 \pm 0.2$ eV) than in $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ ($\Delta E_{\text{ex}} = 3.3 \pm 0.2$ eV), as shown in Table I. We note that the observed exchange energy in $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ is in good agreement with that ($\Delta E_{\text{ex}} \approx 3.5$ eV) obtained from band-structure calculations using the local spin-density approximation.⁶ For the Sr-doped manganites, on the other hand, the exchange energy splitting is larger in $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ ($\Delta E_{\text{ex}} = 5.0 \pm 0.2$ eV) than that in $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$. Fourth, we note that the bandwidths of the majority and minority bands are significantly narrower in the LCMO system than those in the LSMO system. Finally, the exchange energies ΔE_{ex} in the perovskite manganites are significantly larger than that in the magnetite Fe_3O_4 ($\Delta E_{\text{ex}} = 0.8 \pm 0.2$ eV), as summarized in Table I.

Next, we consider the physical implications of our tunneling data taken on these HMF epitaxial films. On the issue of increasing ΔE_{ex} with the increasing alkaline doping level in the ferromagnetic state of perovskite manganites, we note that the ratio of Mn^{4+} ions ($e_g^0 t_{2g}^3$) to Mn^{3+} ions ($e_g^1 t_{2g}^3$) increases with increasing x , and that the crystal-field energy splitting between the e_g - and t_{2g} -orbitals results in a larger on-site exchange energy for the Mn^{4+} ions than for the Mn^{3+} ions. Hence, we would expect ΔE_{ex} to increase with increasing x , which is also consistent with the increase of T_C observed for these two LSMO films. However, the magnitude of increase in ΔE_{ex} with increasing x cannot be estimated easily; spin-dependent band-structure calculations will be necessary to obtain theoretical values of ΔE_{ex} for LSMO and to compare those values with our experimental results.

Regarding the enhanced ΔE_{ex} and reduced ΔE_G of the Sr-doped manganites relative to the Ca-doped manganites, we note that the smaller ionic size of Ca^{2+} results in a larger degree of lattice distortion from the ideal cubic structure.²⁰ There are two important consequences of the larger degree of

lattice distortion. First, stronger electron localization occurs near the Ca^{2+} site, thereby increasing the density of localized minority carriers and reducing the density of mobile majority carriers. Hence, the conductivity of LCMO is smaller relative to that of LSMO, and the double exchange interaction between the neighboring Mn^{3+} and Mn^{4+} ions,^{21,22} which is responsible for the ferromagnetism of these doped manganites,^{20–22} is also weakened in the case of LCMO. Both the Curie temperature T_C and the exchange energy ΔE_{ex} therefore decrease with the decreasing alkaline earth ion size, consistent with our experimental observation. Second, a larger deviation from the cubic structure also results in stronger hybridization of the Mn t_{2g} orbital and the oxygen p orbital. The stronger p – d hybridization is believed to enhance the half-metallicity of the manganites,^{4,6} yielding a larger energy gap in the minority bands. This argument would be consistent with the larger ΔE_G observed in LCMO relative to that in LSMO.

Comparing the exchange energy splitting of the perovskite manganites with that of magnetite Fe_3O_4 , we note that the ferromagnetic exchange interaction for $\text{Fe}^{2+}(e_g^2 t_{2g}^4)$ and $\text{Fe}^{3+}(e_g^2 t_{2g}^3)$ at the B site of the spinel lattice⁵ is compensated by the antiferromagnetic exchange interaction between the A and B -site Fe^{3+} ions.⁵ Hence, the resulting exchange energy splitting between the minority (associated with the A -site ions) and majority (at the B site) carriers is significantly reduced, consistent with our experimental observation of a much smaller ΔE_{ex} in Fe_3O_4 than in the manganites.

The above discussion suggests that the tunneling spectra in Figs. 1(a)–1(c) can be well understood in the context of ferro- and ferrimagnetic half-metallicity. Next, we consider the temperature dependence of the tunneling spectra. In the case of $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$, it is easily understood that the energy splitting between the majority and minority bands disappears in the paramagnetic state at room temperature, because $T_C \approx 260$ K. Regarding the absence of room temperature half-metallicity in Fe_3O_4 , we note that magnetite Fe_3O_4 is known to exhibit a sharp Verwey order-disorder transition involving Fe^{3+} and Fe^{2+} ions¹⁰ below the ferrimagnetic-to-paramagnetic transition at $T_C = 850$ K. An energy gap ~ 0.76 eV in the minority bands has been predicted from the band-structure calculations.^{3,5} However, the presence of disorder above the Verwey transition temperature $T_V \sim 120$ K may result in smearing of the energy gap in the minority subbands, and hence the loss of half-metallic characteristics. This scenario is consistent with the NMR measurements of the longitudinal spin relaxation rate $(1/T_1)$,¹¹ where anomalous temperature dependence of $(1/T_1) \sim T^{5/2}$ for the HMF disappears and a typical metallic dependence of $(1/T_1) \sim T$ is recovered at $T_V < T \ll T_C$. Recent magnetization and magnetoresistance measurements of Fe_3O_4 epitaxial films also indicate the occurrence of the Verwey transition T_V at about 120 K.¹²

On the other hand, the disappearance of room-temperature (below T_C) energy splitting between the majority and minority bands in both Sr-doped manganites is not easily comprehensible. This observation is nonetheless consistent with a recent finding of temperature-dependent spin-

resolved photoemission spectroscopy on $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$,²³ where the difference between the spin density of states of the majority and minority bands decreases linearly with increasing temperature, even at temperatures well below T_C . The rapidly vanishing half-metallic ferromagnetism with increasing temperature from the surface-sensitive photoemission measurements has been attributed to the existence of surface magnetization in LSMO, which may be significantly different from the bulk magnetization. Since STM measurements are also surface sensitive, our results may also be representative of the surface magnetization, and therefore not inconsistent with the bulk half-metallic properties. This issue awaits further quantitative investigation as a function of temperature.

The research at Caltech is supported by the Packard Foundation and the National Aeronautics and Space Administration, Office of Space Science (NASA/OSS). Part of the research was performed by the Center for Space Microelectronics Technology, Jet Propulsion Laboratory, Caltech, and was sponsored by NASA/OSS.

The effect of ^{16}O – ^{18}O isotope exchange on the electric resistivity was studied for $(\text{La}_{1-y}\text{Pr}_y)_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ ceramic samples. It was found that at $y=0.75$, the substitution of ^{16}O by ^{18}O results in the reversible transition from a ferromagnetic metal (FM) to charge ordered (CO) insulator at zero magnetic field. The applied magnetic field ($H \geq 2$ T) transformed the sample with ^{18}O again to the metallic state and caused the increase in the FM transition temperature T_C of the ^{16}O sample. As a result, the isotope shift of T_C at $H=2$ T was as high as 63 K. Such unique sensitivity of the system to oxygen isotope exchange, giving rise even to the metal-insulator transition, is discussed in terms of the isotope dependence of the effective electron bandwidth which shifts the balance between the CO and FM phases. © 1998 American Institute of Physics. INTRODUCTION

The perovskite manganites $\text{R}_{1-x}\text{M}_x\text{MnO}_3$ (Ref. 1), (R^{3+} is a rare earth cation, M is a doubly charged cation with a large ionic radius, attract considerable current interest owing to the recent discovery of colossal negative magnetoresistance (CMR). These materials are characterized by a strong interplay of structural, orbital, and spin degrees of freedom dramatically affecting their transport properties. The important role of the electron-lattice interaction was pointed out in Ref. 3. There are a number of factors contributing to these interactions, including the Jahn-Teller nature of Mn^{3+} ions, the strong dependence of electron transfer on the Mn-O-Mn bond angle,^{4,5} trapping of charge carriers due to the optical breathing mode, and different polaronic effects.

Another feature of the perovskite manganites is the possible formation of the charge ordered (CO) state, manifesting itself in localization of charge carriers accompanied by the regular arrangement of Mn^{3+} and Mn^{4+} ions.⁶⁻⁸ The CO state is usually characterized by semiconductorlike and antiferromagnetic behavior and is accompanied by lattice distortions. Such an ordering, characteristic of $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.2-0.5$), was actively studied recently.^{7,8}

The significant role of electron-lattice interactions in manganites is confirmed by a pronounced isotope effect on the electrical and magnetic properties: in $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$ the isotope shift of the Curie temperature was as large as 21 K.^{9,10} The isotope effect should be even more pronounced in the vicinity of lattice instability related to the charge ordering. Bearing this in mind, we studied the effect of oxygen isotope substitution on the electrical resistivity of a mixed

compound $(\text{La}_{1-y}\text{Pr}_y)_{0.7}\text{Ca}_{0.3}\text{MnO}_3$. By varying the relative contents of Pr and La (i.e., changing the average radius of the rare earth ion) it is possible to obtain the different types of low-temperature behavior [from the ferromagnetic metal (FM) $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ to the charge-ordered antiferromagnetic (AF) insulator $\text{Pr}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$].^{4,11}

The isotope effect in electrical resistivity which we observed for $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{MnO}_3$ ($y=0.75$) samples appeared to be far in the excess of our expectations since the ^{16}O – ^{18}O exchange resulted not only in the significant lowering of the Curie temperature, but also in the metal-insulator transition.

EXPERIMENT

The preparation of the ceramic samples is described in Ref. 2. X-ray diffraction (XRD) showed that the $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{MnO}_3$ ceramic samples produced were of single phase with an orthorhombic structure [lattice parameters $a=0.5436(2)$ nm, $b=0.5461(2)$ nm, $c=0.7686(3)$ nm at 300 K].

The $(\text{La}_{1-y}\text{Pr}_y)_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ system appeared to be convenient for oxygen isotope substitution since its oxygen stoichiometry depends only slightly on variations in the thermal treatment conditions (temperature and partial pressure of O_2). The method used for oxygen isotope substitution ^{16}O – ^{18}O in the selected manganite was similar to that utilized for high-temperature superconductor ceramics.¹³ Two $1 \times 1 \times 8$ mm³ bars were cut from the sintered pellet of $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{MnO}_3$. Both samples were treated simultaneously: one sample was heated in $^{16}\text{O}_2$ atmosphere, the other sample was heated in $^{18}\text{O}_2$ (the molar fraction of $^{18}\text{O}_2$ was 85%) for 48 h at 950 °C under oxygen pressure of 1 bar. The ^{18}O content in the samples was determined by measure-

FIG. 1. Temperature dependence of resistivity for ^{16}O and ^{18}O samples of $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{MnO}_3$ before and after oxygen backexchange.

ment of the weight change of the samples after the isotope enrichment. As a result, the completeness of the isotope exchange was verified.

The electric resistivity was measured by the standard four-probe technique at temperatures down to 4.2 K. The highest resistance that could be measured with the experimental setup was 1 GΩ. The resistivity measurements in the magnetic field applied along the bar sample were performed only during the cooling stages. The magnetic properties were not measured in the current study, thus the assignment of the magnetic states was qualitative and based on experimental data for similar compounds published earlier.^{6-8,13}

RESULTS

The temperature dependence of resistivity $\rho(T)$ in zero magnetic field for the $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{MnO}_3$ samples is shown in Fig. 1. The resistivity curves for samples treated in $^{16}\text{O}_2$ and $^{18}\text{O}_2$ differ drastically. The ^{16}O sample exhibits a clearly pronounced resistivity peak at $T_C = 95$ K associated with transition to the FM state. This value of T_C is in good agreement with Ref. 4. For the ^{18}O sample the resistivity increases monotonically with decreasing temperature and attains about $10^8 \Omega \text{ cm}$ at 50 K, below which the $\rho(T)$ value is so large that it exceeds our measuring limit. This behavior can be attributed to the charge-ordered state which is usually responsible for such an increase in the resistivity.¹³

To make sure that the effect is due precisely to the isotope exchange, we carried out an isotope backexchange. The completeness of the exchange was proved again by changing the sample weight. The sample, which had been first saturated by ^{18}O and was insulating thereafter, became metallic below 95 K after subsequent annealing in $^{16}\text{O}_2$. Correspondingly, the sample that had been first treated in $^{16}\text{O}_2$ and was metallic below 95 K thereafter became an insulator after the subsequent treatment in $^{18}\text{O}_2$ (Fig. 1).

Application of the magnetic field is known to provide melting of the CO state in $(\text{La}_{1-y}\text{Pr}_y)_{0.7}\text{Ca}_{0.3}\text{MnO}_3$, resulting in a metamagnetic phase transition with a drastic decrease of the electric resistivity.^{4,11} This is a magnetic transition of the first order, exhibiting a pronounced temperature hysteresis.

FIG. 2. Temperature dependence of resistivity for ^{16}O and ^{18}O samples of $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{MnO}_3$ in different magnetic fields. The solid line is for the ^{16}O sample; the dashed line is for the ^{18}O sample.

To avoid hysteresis the samples were heated above 150 K, then cooled in the applied magnetic field.

Temperature dependencies of resistivity $\rho(T)$ in the magnetic field are shown in Fig. 2. We found that a magnetic field of 1 T was not enough to suppress the CO state in $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{Mn}(\text{}^{18}\text{O}_{0.85}\text{}^{16}\text{O}_{0.15})_3$ in spite of the more than 30 K upward shift of T_C in the case of $\text{La}_{0.175}\text{Pr}_{0.525}\text{Ca}_{0.3}\text{Mn}(\text{}^{16}\text{O})_3$. Nevertheless, in a field of 2 T melting of the charge-ordered state was clearly demonstrated (Fig. 2).

The isotope shift of T_C was as large as 63 K in a field of 2 T and 54 K in a field of 3 T, which is considerably larger than isotope effects ever reported for $\text{R}_{1-x}\text{M}_x\text{MnO}_3$. It is of note that T_C grows significantly with the increase of the applied magnetic field for both samples. The $\rho(T)$ curves at higher temperature are nearly independent of the isotope exchange (Fig. 2).

Under an external field of 2 T, the resistivity drops by more than seven orders of magnitude to $\rho_{2\text{T}} = 1.5 \Omega \text{ cm}$ at 50 K, exhibiting one of the largest magnitudes of CMR (10^7). For the ^{18}O sample the large decrease in ρ , and thus CMR, can be related to the field-induced melting of the CO state. For the ^{16}O sample the magnitude of the CMR is much less (10^4 for $H = 2$ T).

Note the striking difference between the results for CMR in the ^{16}O and ^{18}O samples. In the ^{16}O sample metallic conduction and ferromagnetism occur spontaneously below the Curie temperature T_C . CMR arises from the abrupt increase in electron hopping via DE at the onset of the spontaneous FM ordering. Sizable CMR exists in the vicinity of T_C . In the ^{18}O sample neither metallic conduction nor ferromagnetism is observed in zero field. CMR originates from the field-induced simultaneous semiconductor-metal and AF-FM transitions.

DISCUSSION

The samples studied in current research lie close to the FM-CO phase boundary and a relatively small influence can in principle transform one state into another, this can be achieved even by isotope substitution.

The relative stability of different phases is determined

mainly by the electron bandwidth or the effective hopping integral t_{eff} . The CO state is favored in the situation when t_{eff} is small enough.^{4,5} One can show this for a simple case of one electron per two sites using the model initially formulated for magnetite,^{14,15} which takes into account the Coulomb repulsion V of electrons at neighboring lattice sites. Its Hamiltonian has the form

$$H = t \sum_{\langle i,j \rangle} a_i^+ a_j + \frac{V}{2} \sum_{\langle i,j \rangle} n_i n_j, \quad (1)$$

where a_i^+ and a_i are creation and annihilation operators for an electron at the i th site, $n = a^+ a$, and $\langle \dots \rangle$ means the summation over the nearest neighbors. On-site Coulomb interaction U is assumed to be the largest parameter, $U \rightarrow \infty$.

The standard mean-field treatment shows¹⁵ that the CO state occurs if the hopping integral t is less than a certain critical value, $t < t_c = Vz/2$ (z is the number of nearest neighbors). The CO critical temperature is given by the expression

$$T_{\text{CO}} \approx Vz \sqrt{1 - (t/t_c)^2} \quad (2)$$

and is reduced with the increase of t , especially strongly for $t \approx t_c$. Thus, the increase of the hopping integral t destabilizes the CO phase.

The t_{eff} value is determined by averaging t over corresponding lattice vibrations that, in turn, depend on the isotope composition of the material. In the simplest case: $t(r) \propto \exp(-\alpha r)$ and

$$t_{\text{eff}} = \langle t \rangle = t_0 \left(1 + \frac{1}{2} \alpha^2 \langle u^2 \rangle \right), \quad (3)$$

where the interatomic distance $r = r_0 + u$, $t_0 = t(r_0)$, and $\alpha \propto 1/r_0$. The mean-square displacement $\langle u^2 \rangle$, and hence t_{eff} , depend on the ionic mass M (even at $T=0$ due to the zero-point vibrations). In case of dominant contribution of zero-point vibrations, we have

$$\langle u^2 \rangle = \hbar / (2M \Theta_D) = \hbar / [2(BM)^{1/2}]$$

where B is the bulk modulus. Thus

$$\delta t_{\text{eff}} \approx -t_0 (\langle u^2 \rangle / r_0^2) (\delta M / M). \quad (4)$$

The corresponding change in t_{eff} is generally not large, especially taking into account that we have to use the reduced mass instead of the pure ionic mass. But this change may still be sufficient to shift our system from one state to another if we are close to the phase boundary at the phase diagram, which is apparently the case in our system. In this situation $t \approx t_c$ and, as follows from Eq. (2),

$$\delta T_{\text{CO}} \propto \delta t / \sqrt{1 - (t/t_c)^2}. \quad (5)$$

Note that in Eq. (2) the typical values of the intersite Coulomb repulsion $Vz \approx 1$ eV (10^4 K), while $T_{\text{CO}} \sim 10^2$ K; hence the square roots in (2) and (5) are of the order of 10^{-2} . Thus, $\delta T_{\text{CO}} \propto \delta t \times 10^2$, and it is not surprising $\delta T_{\text{CO}} \propto \delta t \times 10^2$ that even a relatively small variation of t_{eff} caused by isotope substitution leads to such a drastic change in properties.

The effect discussed above may be strongly enhanced if the charge carriers have polaronic nature. In this case the polaronic band narrowing gives

$$t_{\text{eff}} = t_0 \exp(-E_{\text{pol}}/\omega) \propto t_0 \exp(-\text{const}/\sqrt{M}) \quad (6)$$

and in the specific case considered here it is the oxygen mass that enters Eq. (6).¹⁶

Another factor which may play a role in this effect is possible change of the Mn–O–Nm angle which can also influence t_{eff} .

CONCLUSIONS

The electric resistivity of $(\text{La}_{1-y}\text{Pr}_y)_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ ceramics demonstrates very high sensitivity to the oxygen isotope exchange. At $y=0.75$, the samples with ^{16}O are metallic at low temperatures, while substitution of ^{16}O by ^{18}O results in the insulatorlike behavior. The magnetic field exceeding 1 T restores the metallicity, but the isotope shift of the resistivity peak is very large, 63 and 54 K at $H=2$ and 3 T, respectively.

We argue that this effect is caused by modification of the effective hopping integrals and the resulting electron bandwidth due to isotope substitution, which shifts the relative stability of the CO versus FM states and leads to a transition between these phases. Simple model considerations suggest a significant enhancement of the isotope effect near the onset of the charge-ordered state and the corresponding lattice instability. To analyze this problem quantitatively we must take into account a whole set of competing mechanisms: electron–phonon interaction, polaronic band narrowing, the Jahn–Teller effect, double exchange, intersite Coulomb repulsion of electrons, etc. Nonetheless, we think that our simple arguments correctly describe the main physics of the phenomenon observed.

In this work we present low-field magnetic measurements on multilayers of Fe 1.5 nm and Cu 1.5 nm layers, repeated 10 times, grown on Si(111) and Fe 5 nm/CaF₂ 40 nm/Si(111) substrates. Magnetic characteristics of a spin-glass phase are exhibited by samples directly grown on Si(111), for which the glass temperatures (T_G) depend strongly on the magnetic field. Above T_G those samples exhibit a ferromagnetic behavior. In contrast, samples grown on Fe/CaF₂ buffer structure also show the spin-glass characteristics, but are antiferromagnetic above T_G . This work deals with the fundamental role played by the interface between Fe and Cu for these effects, which is clearly emphasized by the experimental results. © 1998 American Institute of Physics. [S0021-8979(98)46011-0]

Research and development of metallic magnetic multilayers is an area of increasing interest, not only for the fundamental physics involved with films and layers, but especially due to its great potential for a variety of applications. Fe/Cu multilayers are very interesting systems exhibiting a strong correlation between magnetic and structural properties. For example, it is well known that face centered cubic (fcc) γ -Fe and body centered cubic (bcc) Cu metastable phases can be obtained in epitaxial or highly textured films.¹⁻¹⁰ Experimental results and first-principle magnetic structure calculations confirmed that a rich variety of magnetic configurations can be stabilized in fcc γ -Fe with a lattice constant range near that of fcc Cu.¹¹⁻¹⁵ It has also been shown that the magnetic anisotropy energies are rather different for the ferromagnetic and various antiferromagnetic configurations in fcc Fe.^{11,12} Fe/Cu multilayers also present antiferromagnetic exchange coupling which is accompanied by moderate magnetoresistive and magneto-optic effects for chemical modulation periods in the nanometer length scale.¹⁶ Despite of the great interest on magnetic properties of Fe/Cu multilayers, its low-field magnetic susceptibility behavior has not been thoroughly explored in the literature.

The present article reports on the irreversible behavior exhibited by zero-field-cooled (ZFC) and field-cooled (FC) magnetization curves of highly oriented Fe/Cu multilayers. Our experimental results are discussed assuming that a magnetic metastable phase occurs at the interfaces due to the existence of some interdiffusion between Fe and Cu.

Previous studies¹⁷⁻¹⁹ have shown that highly oriented Fe(110)/Cu(111) multilayers consisting of successive depo-

sition of Cu 1.5 nm and Fe 1.5 nm layers repeated 10 times can be grown directly either on Si(111) or on Fe 5 nm/CaF₂ 40 nm/Si(111) substrates. X-ray diffraction and electron diffraction analyses confirmed that the Fe/Cu multilayers grown on Fe/CaF₂ buffer structure have a better structural quality than those grown on Si(111) surfaces. Besides, x-ray reflectivity data reveal that each of these multilayers exhibits rather different interfacial roughness. The samples investigated in this study belong to a series widely explored so far. Despite the wide range of layer thicknesses in the series, we found no meaningful way to explain the very low magnetoresistance in these multilayer systems.

The dc magnetic susceptibility (χ_{dc}) measurements, performed in the temperature range 5–400 K and fields up to 1 kOe, were taken with a superconducting quantum interference device (SQUID) magnetometer (MPMS-5S, Quantum Design). Each measurement resulted from two sample scans over a length of 4 cm, with 40 point readings per scan. Low-field susceptibility measurements as a function of the temperature for different values of the applied field, were carried out using a routine combining a ZFC warming run followed by a FC experiment. To start the procedure, the sample was first heated up to 400 K and then cooled down to 5 K in the absence of magnetic field. Magnetization loops were also measured for many temperatures in between 5 and 400 K. Remnant demagnetization cycles were done at 400 K to prevent spurious irreversible effects associated with magnetic history of the sample in the ZFC measurements. Real and imaginary parts of the low-field ac susceptibility ($\chi_{ac} = \chi' + j\chi''$) of the samples were also measured using the SQUID

FIG. 1. Hysteresis loops measured for sample 2, at temperatures (○) 5 and (●) 300 K.

magnetometer with an excitation field $h_{ac} = 3.0$ Oe. The temperature dependence χ_{ac} at different frequencies was measured while heating the samples.

Figure 1 shows the central portion of hysteresis loops, measured at 5 and 300 K, for one of the Fe/Cu multilayers investigated, grown on a Fe/CaF₂ buffer structure (sample 2). Notice that, at 200 Oe, the relative magnetization is about 95% of its saturation value. Hysteresis loops for the other multilayer studied here, grown on a Si(111) surface (sample 1), are similar and will appear in another publication.¹⁷ Both samples exhibit typical ferromagnetic behavior, saturating at

relatively low magnetic fields. It is worth mentioning that the remnant magnetization values measured at 5 and 300 K for sample 2 are smaller than those observed for sample 1.

Figure 2 shows measurements of χ_{dc} for those two multilayers. One can see that both exhibit a spin-glasslike behavior at low magnetic fields, manifested by several typical signatures, including a field-dependent irreversible magnetization, a frequency dependent χ_{ac} , and the occurrence of metastable states characterized by a logarithmic time relaxation upon application or suppression of external fields of low magnitude.

The irreversible behavior is relatively weak, being more pronounced for sample 2. Besides, the irreversibility temperature associated with the bifurcation in the ZFC/FC curves is quite high and strongly dependent on the applied magnetic field. A glass temperature T_G , associated with a hump in the ZFC curve, is also observed for low fields. Another important feature when comparing these multilayers is that the FC curves for low fields are clearly different. While the FC response for sample 1 resembles those of a ferromagnet, sample 2 exhibits a more complex behavior, including antiferromagnetism for higher temperatures, bounded by a local maximum of χ_{dc} on the vicinity of 380 K. Since the crystal structure of both multilayers is similar, exhibiting identical orientation along the film growth axis, one would conclude that irreversibility comes from the occurrence of dissimilar interfaces in different samples. This magnetic behavior seems to be related to a certain roughness at the Fe/Cu interfaces, which manifests itself as a local intermixing of adjacent layers. Our results suggest that the width of the

FIG. 2. Temperature dependence of χ_{dc} for sample 2 at fields: (a) 10, (b) 50, and (c) 1000 Oe; and for sample 1: (d) 10, (e) 50, and (f) 1000 Oe. Two curves are shown for each value of the field: the lower (○) is for the multilayer zero-field cooled to 5 K while the upper (△) is for the film cooled in the measuring field. Irreversibility temperatures associated with a bifurcation in ZFC/FC curves are observed.

FIG. 3. Temperature dependence of χ' for sample 2. A small memory effect, dependent on the frequency, is present.

mixed interfacial region should be small, involving only a few number of monolayers. Otherwise, one could not explain the ferromagnetic and antiferromagnetic behavior of FC curves.^{20,21}

Figure 3 shows $\chi'(T)$ for sample 2, whereas $\chi''(T)$ appears in Fig. 4. Both exhibit the expected frequency dependence for a spin-glass system.²² χ' shows a typical frequency shift, while χ'' has a maximum which also shifts towards high temperatures. An interesting feature of Fig. 3 is the flatness of χ' between 200 and 350 K which might be evidencing a possible overlapping of spin-glass and antiferromagnetic phases. Also noticeable is the increase in χ'' dispersion for higher frequencies, which could be attributed to an enhanced activity of magnetic domains induced by the rapidly varying excitation field.

In summing up, we have reported clear experimental evidences of a spin-glass behavior overlapping with ferro- and antiferromagnetism in Fe/Cu multilayers. As a matter of fact, a detailed investigation of the microscopic character of the interfaces in the samples of interest is a crucial task in the study of the mechanisms leading to the behavior reported here. In the past we have employed x-ray reflectivity with a double-crystal setup and also conventional θ - 2θ low-angle diffraction, in an attempt to clarify those questions. Other powerful techniques, like *in situ* transmission, tunneling, and atomic force microscopy, could represent an expressive step forward in this subject, but neither is available at the moment. We are now conducting an alternative study, to appear soon elsewhere, in which we change the number of interfaces and the surface/volume ratio.

Furthermore, there is an still unpublished work resulting from near-edge extended x-ray absorption fine structure experiments conducted at LURE (Orsay, France) on these multilayers, which indicates the existence of highly disordered Cu sites at the interfaces, corroborating the proposed scenario of local intermixing and roughness at adjacent layers.

As we see, a considerable amount of information on the structure of these systems has been collected in this and in previous work, indicating that the Fe/Cu interface peculiari-

FIG. 4. Temperature dependence of χ'' for sample 2. Typical frequency shifts of χ'' peaks are observed.

ties are to be responsible for the presently reported behavior, as well as for the absence of significant giant magnetoresistance effects in these multilayers.¹⁹

The composition with $x=0.15$ in the spin glass regime ($0 \leq x \leq 0.18$) of the perovskite system, $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$, is investigated in detail to understand the unusual magnetic properties reported in the literature. AC susceptibility and field-cooled and zero-field-cooled magnetization measurements give sufficient evidence for compositional inhomogeneity as the origin of the magnetic anomalies. A well-defined spin glass behavior is obtained only for a highly homogeneous sample. © 1998 American Institute of Physics. [S0021-8979(98)32311-7]

I. INTRODUCTION

The perovskite system, $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$, has been studied extensively in the recent past to understand the evolution of its unusual electronic properties. Jonker and van Santen¹ first reported that the paramagnetic Curie temperature increases from negative to positive value for $x > 0.1$ and the onset of ferromagnetism is caused by the $\text{Co}^{3+}-\text{O}-\text{Co}^{4+}$ double exchange interaction as proposed by Zener.² From detailed studies on the magnetic properties, Itoh *et al.*³ have reported that there is no true long range ferromagnetic ordering as reported previously and there exists spin glass for $0 \leq x \leq 0.18$ and cluster glass for $0.18 \leq x \leq 0.5$ regions in $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$. Senaris-Rodriguez and Goodenough⁴ recently reported the superparamagnetic blocking model to explain the unusual magnetic behavior of their low Sr-doped samples.

Most of the unusual behavior observed for the $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ system is in the spin glass composition regime. For example, a spin glass freezing temperature of 65 K with a well-defined cusp-like magnetization behavior is reported by Itoh *et al.*³ for $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ whereas recent investigations^{4,5} on the same composition showed multiple magnetic transitions; (i) a Curie temperature of ~ 240 K due to ferromagnetic ordering within large magnetic clusters, (ii) a shoulder-like transition at ~ 170 K due to blocking of these larger clusters below which the field cooled and zero field cooled magnetization shows irreversible behavior, and (iii) a spin glass freezing at ~ 70 K which is due to the final collective blocking of small clusters. Though blocking of large clusters takes place at ~ 170 K, there was no cusp in the ac susceptibility observed at this temperature.

We have investigated the origin of this unusual magnetic behavior of the spin glass composition $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ using ac magnetic susceptibility and dc magnetization studies. Our studies are based on the fact that the above interesting results are obtained from measurements on samples processed at different heat treatment conditions.

II. EXPERIMENT

$\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ samples were prepared by the high-temperature ceramic (solid-state reaction) and by the low-temperature coprecipitation methods. In the ceramic method, molar ratios of La_2O_3 (preheated at 1000°C), SrCO_3 and $\text{CoC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, are mixed together and calcined at 950°C . The calcined sample was heated at 1000°C for 72 h with six intermediate grindings. The bulk sample was then pressed into pellets and annealed at different temperatures in the range 1000 – 1300°C . Low-temperature synthesis by the coprecipitation method was performed following the reported method.^{4,5} The mixed hydroxide precipitate was initially decomposed at 750°C and then annealed at different temperatures. The oxygen stoichiometry of all the samples were determined by oxidation-reduction titrations using potassium permanganate and ferrous sulfate solutions and were stoichiometric ($\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_{3 \pm 0.01}$). The microstructural features were obtained using a Leica-Cambridge 440 Scanning Electron Microscope (SEM). AC magnetic susceptibility (27 Hz, 10 Oe) was measured by the mutual inductance method in an APD close-cycle helium cryostat (15 – 300 K). Field-cooled (FC) and zero-field-cooled (ZFC) dc magnetization ($H_A = 100$ Oe) studies were done on a EG&G PAR VSM model 4500 fitted with a Janis liquid nitrogen cryostat (80 – 300 K).

III. RESULTS AND DISCUSSION

Figure 1 shows the ac susceptibility curves of the sample prepared by the ceramic method and annealed at different temperatures. The sample annealed at 1000°C for 72 h shows a magnetic transition at $T_c \approx 250$ K and this transition temperature shifts to lower temperatures as the annealing temperature is increased. All the curves show a second magnetic transition immediately below the first transition and a maximum in the susceptibility is observed at $T = T_{\chi_{\text{max}}}$, which also decreases continuously with increasing annealing temperature. As T_c is decreased, the magnitude of susceptibility at T_c is also decreased and finally a cusp-shaped magnetic susceptibility curve is obtained at $T_g = 75$ K.

FIG. 1. AC susceptibility curves of $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ synthesized by the ceramic method and annealed at different temperatures. (1) 1000 °C/72 h, (2) 1050 °C/12 h, (3) 1100 °C/12 h, (4) 1100 °C/24 h, (5) 1100 °C/48 h, (6) 1150 °C/12 h, (7) 1200 °C/12 h, (8) 1250 °C/12 h, (9) 1300 °C/12 h. Inset: ac susceptibility curves of (a) $\text{La}_{0.5}\text{Sr}_{0.5}\text{CoO}_3$ and (b) $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ samples prepared by the ceramic method annealed at 1000 °C/72 h.

In the inset of Fig. 1, the ac susceptibility curve of $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ annealed at 1000 °C (curve 1 in Fig. 1) is compared with that of $\text{La}_{0.5}\text{Sr}_{0.5}\text{CoO}_3$ processed under identical conditions. In $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ system, maximum ferromagnetic Curie temperature is observed for $x=0.5$.¹ Both these curves are identical, showing a sharp transition at ~250 K, with the maximum value of susceptibility for the $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ composition approximately 1/5th of that of the $\text{La}_{0.5}\text{Sr}_{0.5}\text{CoO}_3$ sample. It appears that the $x=0.15$ composition annealed at 1000 °C contains a minimum of ~20% of the $x=0.5$ composition. This implies that the low temperature annealed $x=0.15$ sample is highly compositionally inhomogeneous. This sample may contain various phases of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ having different x values. On further annealing of the sample at higher temperatures, the sharp magnetic transition is shifted to lower temperatures indicating narrowing down of the compositional range and finally a well-defined magnetic transition is obtained for the high temperature annealed sample.

The FC and ZFC curves of two samples prepared by the ceramic method are shown in Fig. 2. The nature of the FC and ZFC curves of both the 1000 and 1100 °C annealed samples are similar to that reported for the sample prepared by coprecipitation method.⁵ The ferromagnetic composition $\text{La}_{0.5}\text{Sr}_{0.5}\text{CoO}_3$ also shows similar behavior which is assigned to the cluster-glass nature of the compound.^{3,6} Inset in Fig. 2 compares the identical nature of the ZFC and ac susceptibility curves of the sample annealed at 1100 °C. The ac susceptibility curve of the sample annealed at 1300 °C is similarly identical to that of the ZFC curve reported by Itoh *et al.*³

Figure 3 shows the FC and ZFC curves of the sample prepared by the coprecipitation method. The sample heated to 750 °C shows behavior similar to that of the ceramic sample annealed at 1000 °C showing a magnetic transition below ~250 K. The ZFC curves of the ceramic sample an-

FIG. 2. FC (solid symbols) and ZFC (open symbols) curves of $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ ceramic samples annealed at 1000 °C/72 h (squares) and 1100 °C/24 h (circles). Inset: (a) ac susceptibility and (b) ZFC curves of the 1100 °C/24 h annealed sample showing identical nature of the curves.

nealed at 1100 °C/24 h and the coprecipitated sample annealed at 1000 °C are compared in the inset. Both the curves show an initial magnetic transition below ~240 K and a maximum in the magnetization below ~200 K. The particle sizes obtained from SEM for the above samples were ~1000 and ~200 nm, respectively. However, the T_c and the magnitude of the magnetization at T_c of the coprecipitated sample is lower than that of the ceramic sample indicating that the contribution due to the Sr-rich phase is less in the coprecipitated sample. This sample also shows an increase in magnetization below ~100 K which marks the formation of the required composition at this processing temperature. ZFC curves of the coprecipitated sample annealed at different temperatures are compared in Fig. 4. As in the case of the ceramic samples, the increase in annealing temperature decreases the contribution due to the Sr-rich phase as well as narrow down the compositional range. The behavior of this

FIG. 3. FC (solid symbols) and ZFC (open symbols) curves of $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ sample prepared by the coprecipitation method and annealed at different temperatures, 750 °C/16 h (squares), 1000 °C/12 h (diamonds), and 1100 °C/12 h (circles). Inset: ZFC curves of the composition prepared by (a) ceramic method 1100 °C/24 h and (b) coprecipitation method, 1000 °C/12 h.

FIG. 4. Comparison of the ZFC curves of the $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ sample prepared by the coprecipitation method, (a) 750 °C/16 h, (b) 1000 °C/12 h, (c) 1100 °C/12 h, and (d) 1200 °C/12 h. Curve (a) refers to the right vertical axis.

sample annealed at 1200 °C is better than that of the ceramic sample annealed at 1300 °C, with no other magnetic transition apart from the slow increase in the magnetization below ~100 K which is due to the contribution from the spin glass phase alone. This implies that the low-temperature synthesized sample if processed at sufficiently higher temperature ensures compositional homogeneity and will show similar spin glass behavior obtained for the sample prepared by the ceramic method and annealed at very high temperatures (Fig. 1). The particle size of the coprecipitated sample annealed at 1200 °C was less than 1000 nm. This shows that the observed differences in the magnetic behavior is not particle size dependent.

The unusual results of Mira *et al.*⁵ and Senaris-Rodriguez and Goodenough⁴ showing multiple magnetic

transitions for the $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ composition is thus due to compositional inhomogeneity rather than due to the cluster size dependence. The transition at ~240 K and the shoulder below ~200 K indicate that the compound contains sufficient amount of phases with composition close to $x=0.5$ ($T_c \approx 245$ K) and $x=0.2$ ($T_c \approx 180$ K). These results may be compared with the ZFC magnetization curves reported by Itoh *et al.*³ and Golovanov *et al.*⁷ for $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$ which show only a cusp at the spin glass freezing temperature. It has been shown earlier from energy-dispersive analysis by x-ray by Baythoun and Sale⁸ and Chick *et al.*⁹ that perovskites with similar compositions synthesized by the sol-gel method are highly compositionally inhomogeneous when processed at low temperatures. It appears that processing conditions are extremely important in determining the true magnetic behavior of perovskite type $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ compounds.

We report magnetic properties of a new class of hybrid organic/inorganic layered materials, $\text{Cu}_2(\text{OH})_3(\text{C}_m\text{H}_{2m+1}\text{COO})$, $m=7, 9$, and 11 . The frequency dependence of the linear ac susceptibility and the irreversibility in the field-cooled/zero-field-cooled magnetization show that the geometrical frustration of the triangular lattice is strong enough to cause glassiness. The strong peak in the second harmonic of the nonlinear ac susceptibility indicates that frustration is not sufficient to prevent the system from developing a spontaneous moment. We propose that the interplay of Heisenberg antiferromagnetic exchange and Dzyaloshinskii–Moriya interaction leads to the unusual coexistence of glassiness and canted antiferromagnetism. © 1998 American Institute of Physics. [S0021-8979(98)46111-5]

I. INTRODUCTION

The question whether geometrical frustration alone, as opposed to random exchange, is strong enough to destroy magnetic order has preoccupied not just the theoretical community¹ but the experimental one as well. Traditionally, spin glass behavior was thought to require both disorder and frustration.^{2,3} It has been argued that frustration alone can lead to large ground-states degeneracies, accompanied by extensive ground-state entropies, but cannot produce a sufficiently “rough” free energy landscape necessary for the development of glassiness.⁴ Since the effects of frustration are more pronounced in lower dimensions, the best candidates for disorder-free glassiness are two-dimensional antiferromagnets on triangular or kagomé lattices.^{1,4} Such systems have been intensely studied in recent years, glassiness being found in kagomé systems⁵ as well as in other materials,^{6,7} all having continuous symmetry spins and sharing the same basic building block—the triangular plaquette—for their lattices.

We recently reported the first evidence for hybrid organic/inorganic triangular quantum Heisenberg antiferromagnets (TQHAF) with weak additional Dzyaloshinskii–Moriya (DM) interaction, $\text{Cu}_2(\text{OH})_3(\text{C}_m\text{H}_{2m+1}\text{COO})$, $m=7, 9$, and 11 .⁸ Based on dc magnetization and magnetic irreversibility studies, and on linear and nonlinear ac susceptibility data we showed that these compounds have an unusual magnetic behavior, inconsistent with both the resonant valence bond (RVB)⁹ and the noncollinear Néel ground state.¹⁰ We suggested that the DM antisymmetric exchange is responsible for the spontaneous moment and Ising-like ordering. We present here further evidence to support our claim that the interplay between the Heisenberg antiferro-

magnetic exchange causing geometrical frustration and the DM interaction leading to spin canting allows these systems to evolve into a new unusual state with both canted antiferromagnetic and glassy characteristics.

II. EXPERIMENT

The samples we have studied are compounds obtained by intercalation of saturated organic chains between inorganic layers of copper hydroxides.¹¹ The copper hydroxy salts $\text{Cu}_2(\text{OH})_3\text{X}$ ($\text{X}=\text{NO}_3$, $\text{C}_m\text{H}_{2m+1}\text{COO}$, $m\geq 0$, etc.) exhibit a botallackite-type structure,¹² in which two-crystallographically distinct copper atoms lie in different octahedral environments.¹¹ X-ray powder diffraction studies revealed layered structures with interlayer distances of 24.1, 29.4, and 34.4 Å for $m=7, 9$, and 11 , respectively.¹¹ Extended x-ray absorption fine structure (EXAFS) measurements showed¹³ that the polycrystalline powder samples of the intercalation compounds maintain the basic framework of the crystalline inorganic layer $\text{Cu}_2(\text{OH})_3\text{NO}_3$, with slight distortions of the local octahedral symmetry. Though it is difficult to put an upper limit to any structural disorder present, transmission electron microscopy photographs of the polycrystalline powders revealed interference patterns usually observed in structurally well ordered materials,¹⁴ and the x-ray diffraction studies indicate crystallites of ~ 300 Å diameter.

The Cu^{2+} ions (no single ion anisotropy) are $S=1/2$ Heisenberg spins located on nonequilateral triangular magnetic lattices.¹¹ The most important interactions consistent with this structure are the Heisenberg (symmetric) superexchange through oxygen atoms and then the DM (antisymmetric) exchange¹⁵ caused by the spin-orbit interactions and the different local environments of adjacent copper sites.¹³ DM interaction recently was shown to be responsible for canted antiferromagnetic behavior in other two-dimensional

FIG. 1. χ'_1 of $\text{Cu}_2(\text{OH})_3(\text{C}_{11}\text{H}_{23}\text{COO})$, in $H_{ac}=1$ Oe (zero applied dc field) at frequencies $5 \leq f \leq 10\,000$ Hz. Inset: χ'_1 of $\text{Cu}_2(\text{OH})_3(\text{C}_m\text{H}_{2m+1}\text{COO})$, $m=7, 9$, and 11 , in $H_{ac}=1$ Oe (zero applied dc field) at $f=5$ Hz.

(2D) oxygen bridged copper systems, the parent compounds for high temperature superconductors.¹⁶

The ac magnetic susceptibility was measured with a Lake Shore 7225 ac susceptometer dc magnetometer in zero dc applied field and in the temperature range $5 \leq T \leq 30$ K, on warming. Both the in-phase (χ'_1) and out-of-phase (χ''_1) linear susceptibilities, $\chi_1 = \chi'_1 + i\chi''_1$, were measured under an ac field $H_{ac}=1$ Oe and a wide range of frequencies ($5 \leq f \leq 10\,000$ Hz). The second and third harmonics of the magnetic susceptibility χ_2 and χ_3 were obtained by reading the $2f$ and $3f$ lock-in responses, respectively, to an ac field with frequency f . The harmonics were measured on warming, in zero applied magnetic field, at fixed ac field amplitude (1.3 Oe) and frequencies between 10 and 3330 Hz. The magnetization was measured with a Quantum Design MPMS 5 superconducting quantum interference device (SQUID) magnetometer for $5 \leq T \leq 350$ K and $0 \leq H_{dc} \leq 55\,000$ Oe.

III. RESULTS AND DISCUSSION

The lowest frequency (5 Hz) χ'_1 data for the three compounds is displayed in the inset of Fig. 1. The independence of the peak temperatures ($T_p=19.1, 19.3$, and 19.0 K, for $m=7, 9$, and 11 , respectively) on the interlayer distances indicates that the magnetic behavior is governed by the intralayer interactions and, therefore, that these compounds are true 2D systems. Also, the relatively sharp peaks of the ac susceptibility suggest divergencies and, therefore, true magnetic transitions.

The peak temperature of χ'_1 increases and the peak height decreases with increasing frequency, Fig. 1, indicative of slow relaxation processes that characterize the glassy behavior.³ The values of the relative variation of the peak

FIG. 2. FC (filled symbols) and ZFC (empty symbols) magnetization of $\text{Cu}_2(\text{OH})_3(\text{C}_{11}\text{H}_{23}\text{COO})$ in dc applied fields of $5 \leq H_{dc} \leq 100$ Oe.

temperature per decade of frequency, $(\Delta T_p/T_p)/\Delta(\log f) = 0.003, 0.008$, and 0.008 , for $m=7, 9$, and 11 , respectively) place these compounds in the range of canonical spin glasses.³ The strength of frustration in these geometrically frustrated systems, estimated from the ratio between the Curie-Weiss mean field ordering temperature Θ_{CW} and the true critical temperature T_c , $f_R = \Theta_{CW}/T_c$,⁷ was found to be 7, 6.5, and 6 for the three compounds, respectively.⁸ These values suggest moderate strength frustration,⁷ however they appear to be enough to cause the slow relaxation processes characteristic for glassy systems.

The field-cooled (FC) and zero-field-cooled (ZFC) magnetization curves for the $m=11$ compound ($m=7$ and 9 compounds have almost identical behavior),^{8,17} Fig. 2, show a rapid rise with decreasing T just above 20 K. At lower T the ZFC magnetization deviates below the FC magnetization indicating history dependence of the magnetization processes in the T range where χ'_1 shows frequency dependence. The field dependence of the bifurcation point T_b between the FC and ZFC curves (T_b decreases with increasing the applied dc field) reinforces the glassy behavior description.³

Even harmonics can be observed only if a system exhibits a spontaneous magnetization, due to the lack of inversion symmetry with respect to the applied field.¹⁸ Only odd harmonics are expected for a spin glass while for ferromagnets both even and odd harmonics should be present.¹⁹ Both second and third harmonics ($2f$ and $3f$ responses, respectively), for the $m=11$ compound, Fig. 3, (the $m=7$ and 9 compounds have almost identical behavior),^{8,17} have sharp peaks suggesting divergencies of both these quantities and, therefore, true magnetic transitions. The peak in the second harmonic indicates that a spontaneous moment is formed at that transition while the frequency dependence of both components of the nonlinear susceptibility suggests slow relaxation processes and glassiness.

Thus, all three systems show very similar magnetic properties. The high temperature TQHAF behavior was pre-

FIG. 3. Nonlinear susceptibilities $|\chi_{2,\text{exp}} H_{\text{ac}}|$ and $|3/4 \chi_{3,\text{exp}} H_{\text{ac}}^2|$ of $\text{Cu}_2(\text{OH})_3(\text{C}_{11}\text{H}_{23}\text{COO})$ measured at $2f$ and $3f$, respectively, in $H_{\text{ac}} = 1.3$ Oe (zero applied dc field) at frequencies $10 \leq f \leq 3330$ Hz.

viously shown by the fit of the static susceptibility to high temperature series expansions. At low temperatures the frequency dependence of the linear ac susceptibility and the field dependence of the bifurcation point of the field-cooled/zero-field-cooled magnetization data suggest slow relaxation and glassiness. The second harmonic of the nonlinear ac susceptibility indicates that geometrical frustration is not strong enough to prevent the system from canted antiferromagnetic type of ordering. Hence, we propose that these are three TQHAF systems with weak additional DM interaction whose unusual behavior is determined by the interplay between the

Heisenberg exchange, causing frustration and glassiness, and the DM exchange, causing spin canting and 2D Ising-like behavior.

Magnetic and structural properties of $\text{PrCo}_{3-x}\text{Si}_x$ compounds

T. Matsui, R. D. Stevenson, R. D. Kirby,^{a)} and D. J. Sellmyer

Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

We have systematically investigated the magnetic properties of the rare-earth compounds PrCo_8Si and $\text{PrCo}_{3-x}\text{Si}_x$, the crystal structures of which are hexagonal CeNi_3 -type and rhombohedral Be_3Nb -type, respectively. Sharp cusps were observed in the real and imaginary parts of the ac susceptibility at temperatures between 282 ($x=0.08$) and 209 K ($x=0.23$). Also observed were bifurcations of the zero-field-cooled and field-cooled magnetization curves at the same temperatures, showing that the magnetization was irreversible below these temperatures. The effect of Si substitution for Co in this system is to decrease the average ferromagnetic exchange interaction, thus decreasing the Curie temperature, without introducing significant random magnetism effects due to exchange fluctuations or random magnetic anisotropy. © 1998 American Institute of Physics. [S0021-8979(98)46211-X]

I. INTRODUCTION

Considerable effort has been devoted to understanding disordered magnetic systems which can result from exchange fluctuations or random anisotropy.¹⁻³ Letting \mathbf{S}_i be the spin vector at site i and \mathbf{n}_i be a random unit vector whose direction varies independently from site to site, the Hamiltonian describing the system can be written

$$H = -\sum (J_0 + \Delta J_{ij}) \mathbf{S}_i \cdot \mathbf{S}_j - D \sum (\mathbf{n}_i \cdot \mathbf{S}_i)^2, \quad (1)$$

where J_0 is an average exchange interaction, ΔJ_{ij} is the fluctuations in the exchange interactions, and D is a measure of the strength of the random anisotropy.⁴ For real materials, both exchange fluctuations and random anisotropy should be taken into consideration. In the case of $D \approx 0$, for example materials containing isotropic rare-earth elements, there is a possibility for a spin-glass phase (SG) or a re-entrant spin glass phase (RSG) as a disordered state. However, if ΔJ_{ij} is negligible compared to D , a random magnetic anisotropy (RMA) glass phase may appear. In such a case the above equation becomes the Harris-Plischke-Zuckermann Hamiltonian on which much of the theory of the RMA problem is based.⁵ Almost all of the materials studied previously can be classified as either SG or RMA, which avoids difficulties in separating an exchange-fluctuation effect and a random-anisotropy effect.

In this study we have sought to investigate the above effects in an intermetallic compound system, $\text{PrCo}_{3-x}\text{Si}_x$, in which one expects strong single-ion anisotropy from the Pr, and a weakening average exchange (J_0) from the Si doping. The presence of any randomness is anisotropy or significant exchange fluctuation was also a subject for study.

II. EXPERIMENTAL PROCEDURE

Bulk samples of $\text{PrCo}_{3-x}\text{Si}_x$ ($x=0.0-0.23$) were prepared by arc melting in purified argon gas. The starting elements all had purity higher than 99.9%. The compositions of

the samples were determined from the initial weights of the component elements and checked by weighing after melting. The alloys were subsequently homogenized for 100 h at 800 °C in vacuum. The crystal structures were determined by x-ray diffraction using $\text{Cu } K\alpha$ radiation and a graphite monochromator. The magnetization was measured by a Faraday balance and a superconducting quantum interference device (SQUID) magnetometer over the temperature range from 5 to 500 K. Powdered samples were used for SQUID measurements so that individual grains could rotate freely along the direction of the applied magnetic field. The ac susceptibility measurements for the bulk samples were performed with a driving frequency between 10 and 1600 Hz and a driving field of 1 Oe.

III. RESULTS AND DISCUSSION

Figure 1 shows the x-ray diffraction scans for the $\text{PrCo}_{3-x}\text{Si}_x$ samples with various x values. It is found that the pattern for the $x=0.0$ sample was almost entirely single phase PrCo_3 . Upon adding silicon up to $x=0.23$ the diffraction patterns did not change basically except for that a very small peak around $2\theta=44.5^\circ$ (indicated by lower triangle) appeared in some of the alloys. This peak is likely due to ferromagnetic Pr_2Co_7 . However, the effect of this small amount of Pr_2Co_7 on the magnetic properties discussed here could be accounted for easily.

The temperature dependence of magnetization for the $x=0.17$ sample is shown in Fig. 2. After initial zero-field cooling, the magnetization was measured in a 50 Oe applied field as the temperature was raised to 300 K [solid circles in Fig. 2(a)]. A peak at a temperature around 225 K was found. In subsequent cooling in the same applied field, the magnetization followed the same curve until it reached the peak. Below that temperature, it followed another path, showing a thermal hysteresis. The temperature at which the bifurcation of the zero-field-cooled (ZFC) and the field-cooled (FC) magnetization curves appears, decreases with an increasing applied magnetic field, as shown for the case of $H=1000$ Oe in Fig. 2(b).

Figure 3 shows the in-phase (χ') and out-of-phase (χ'') components of the ac susceptibility for the $x=0.17$ sample. Sharp cusps are found in both the χ' and χ'' curves in the same temperature region where the bifurcation appears on the FC and ZFC magnetization curves. It should be noticed that the peak in χ' shifts towards a higher temperature with increasing frequency, suggesting that thermally activated

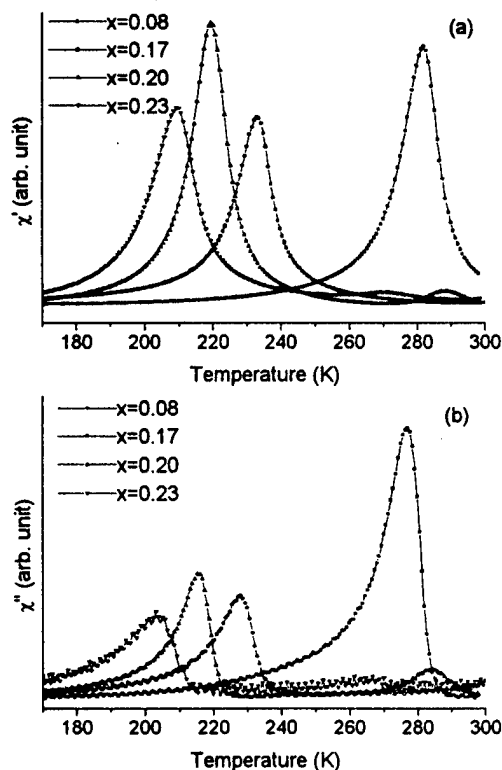

FIG. 4. In-phase (a) and out-of-phase (b) ac susceptibility vs temperature of $\text{PrCo}_{3-x}\text{Si}_x$ for $x=0.08, 0.17, 0.20$, and 0.23.

FIG. 5. Estimated Curie temperature of $\text{PrCo}_{3-x}\text{Si}_x$ as a function of x .

dependence of ac susceptibility was investigated. Figure 4 shows the χ' and χ'' versus temperature curves for the $x = 0.08, 0.17, 0.20$, and 0.23 samples. Sharp cusps appear in both χ' and χ'' curves for all the samples at temperatures between 282 K ($x = 0.08$) and 209 K ($x = 0.23$). Although these measurements could not be extended above 300 K, χ' for the $x = 0.0$ sample increases with temperature up to 300 K, suggesting that it will also exhibit a sharp cusp near the Curie temperature of 339 K. It was also found from the SQUID measurement that the magnetization becomes irreversible below each cusp temperature. The additional small peaks appearing on the high temperature side of the ac susceptibility peak for the $x = 0.20$ and 0.23 samples may be due to the presence of a small amount of the Pr_2Co_7 phase. Magnetization measurements in the $x = 0.0$ sample show an abrupt drop in the magnetization as the temperature increases above 339 K, suggesting the presence of a ferromagneticlike transition at that temperature.

The binary compound PrCo_3 was reported by Yakinthos *et al.*⁶ and Buschow *et al.*⁷ to be ferromagnetic with the easy direction along c axis below the Curie temperature of $T_c = 349$ and 339.5 K, respectively, and our temperature dependent magnetization measurements are consistent with this.

Figure 5 shows the Si-concentration dependence of the Curie temperature as measured by the temperature of the peak in χ' . It can be seen that the decrease with x is clearly

nonlinear in x . In a simple mean-field model $T_c \propto zJ_0$, where z is the number of nearest-neighbor magnetic ions and J_0 is the average exchange of Eq. (1). However, this model is not realistic for $\text{PrCo}_{3-x}\text{Si}_x$ alloys because the exchange interactions are quite sensitive to local environments. (It should be noted that YCo_2 , for example, is not magnetic.⁸) A spin-fluctuation model for which $T_c \propto M_s^2/\chi_0$, where χ_0 is the exchange-enhanced susceptibility, is likely to be more appropriate.⁹ For example, if χ_0 is assumed to be constant and M_s to vary linearly in x , then $T_c(x)$ would change in a nonlinear way as seen in Fig. 5.

The relatively sharp peaks in χ' and χ'' are of interest because they are reminiscent of spin-glasslike freezing due either to random anisotropy or exchange fluctuations. However, in this series of alloys, with relatively small Si doping levels, it seems likely that any such effects are small perturbations on a basically ferromagneticlike system whose positive exchange interactions are weakened by Si addition. The sharp susceptibility peaks can be understood in terms of a model developed by Buschow and Brouha¹⁰ for rare earth-cobalt alloys based on RCo_5 . In such compounds, where there is large single-ion anisotropy due to the rare earths, domain walls can be pinned by the lattice but thermal irreversibilities such as observed in Fig. 2, can be caused by thermally assisted domain-wall motion. This also could lead to the sharp cusps in susceptibility at T_c .

IV. CONCLUSIONS

In summary, $\text{PrCo}_{3-x}\text{Si}_x$ represents a diluted ferromagnetic system with a decreasing exchange and Curie temperature with an increasing Si concentration. The sharp ac susceptibility peaks and nonlinear variation of T_c can be rationalized on the basis of an itinerant spin-fluctuation model and thermally activated pinning of domain walls.

Frustration in the paramagnetic phase of spin-density-wave CrFeV alloys

The magnetic susceptibility $\chi(T)$ of the spin-density-wave (SDW) alloys $(\text{Cr}+2.7\% \text{Fe})_{1-x}\text{V}_x$ ($x=0.07, 0.29, 0.61, 0.9, 1.28$, and 2.0% V) and of the paramagnetic alloys ($x=5$ and 10% V) measured in a field, $H=100$ Oe, in the temperature range, $T=5-400$ K, was found to exhibit hysteresis between the field-cooled and zero-field-cooled states, starting at an irreversibility limiting temperature T_i well above the Néel temperature T_N in the SDW alloys, and also in the paramagnetic alloy $(\text{Cr}+2.7\% \text{Fe})_{95}\text{V}_5$. This behavior is attributed to the frustration of moments on the Cr atoms associated with the formation of a local-SDW phase above the bulk Néel transition. © 1998 American Institute of Physics. [S0021-8979(98)32411-1]

Following the observation¹ of hysteresis with respect to field cooling in the temperature dependence of the magnetic susceptibility $\chi(T)$, measured in a field, $H=100$ Oe, in the spin-density-wave (SDW) alloys $(\text{Cr}+3.2\% \text{Co})_{1-x}\text{V}_x$ ($x \leq 1\%$) at an irreversibility limiting temperature well above the Néel temperature T_N , we have found similar behavior in the corresponding system of CrFeV alloys containing the magnetic impurity Fe.

We note first that the behavior of Fe impurity in Cr and Cr alloys is unique in that the temperature dependence of $\chi(T)$ obeys a Curie–Weiss law, indicating that the Fe atom carries a moment, in the SDW phase as well as in the paramagnetic phase.² SDW CrCoV alloys exhibit a Curie–Weiss paramagnetism only in the paramagnetic phase, and the moment is believed to be frozen in the SDW state.² This difference from the behavior of the CrFeV alloys is however not relevant to the present work, since the onset of irreversibility occurs in the paramagnetic phase. We note also that irreversibility was not observed in other recent work on these CrFeV alloys,³ since the measurements were performed in a relatively high measuring field, $H \geq 1$ kOe, and only in the zero-field-cooled state.

We report here the temperature dependence of $\chi(T) = M(T)/H$, M being the magnetization measured with a SQUID magnetometer MPMS-5S from Quantum Design, of $(\text{Cr}+2.7\% \text{Fe})_{1-x}\text{V}_x$ ($x=0, 0.07, 0.29, 0.61, 0.9, 1.28, 2, 5$, and 10% V; all percentages are atomic) with a measuring field of 100 Oe over the temperature range from 5 to 400 K in the field-cooled (FC) and zero-field-cooled (ZFC) states. The FC measurements were performed after applying the measuring field at $T=400$ K, while cooling (FCC) and then warming (FCW). The experimental procedure and methods of sample preparation and characterization were the same as those followed in Refs. 3 and 4.

No temperature hysteresis of $\chi(T)$ was found between the FCC and FCW states, but all the ternary alloys except $(\text{Cr}+2.7\% \text{Fe})_{90}\text{V}_{10}$ show strong hysteresis between the FC

and ZFC states, as shown in Fig. 1. A distinct anomaly occurs in both the FCC and FCW curves at the temperature where they begin to diverge from the ZFC curve, which is taken to define the irreversibility limiting temperature T_i .

Alloys containing $x \geq 0.29\%$ V show no anomaly in $\chi(T)$ at the Néel temperature T_N [see Fig. 1(c)] perhaps because the SDW becomes commensurate at higher concentrations of V in CrFeV alloys.⁵ We have therefore used the anomaly in the temperature dependence of the resistivity $\rho(T)$ to define $T_N(x)$.⁶

In the CrFeV alloys, just as in CrCoV,¹ $T_i(x)$ decreases like $T_N(x)$ as the concentration x of V increases, but rather less rapidly, as seen in Fig. 2. It is especially interesting to see that there is still strong irreversibility in the paramagnetic alloy $(\text{Cr}+2.7\% \text{Fe})_{95}\text{V}_5$ starting at a high temperature, $T_i=210$ K [see Fig. 1(g)]. For $x=10\%$ V, there is no irreversibility [see Fig. 1(h)] so $T_i(x)$ must vanish somewhere between $x=5$ and 10% V.

It should be noted that, while the difference between the susceptibility in the FC and ZFC states increases in rough proportionality with the V concentration between $x=0.3$ and 2% V, the very small concentration, $x=0.07\%$ V, produces a disproportionately large effect, as illustrated in Fig. 3. A trace of V produces a remarkably large effect also in the CrCoV system.¹

We believe that the well-defined anomaly in the FCC and FCW curves of $\chi(T)$ and the onset of irreversibility at T_i in both the CrFeV and CrCoV systems corresponds to the new magnetic phase transition, which occurs in the paramagnetic phase well above the bulk Néel transition at T_N .¹ The rapid divergence between the FC and ZFC curves of $\chi(T)$ is similar to that seen in SDW Cr alloys containing Mn.^{4,7} In the latter case, however, the irreversibility appears at the so-called pinning temperature in the SDW phase well below T_N , and has been attributed to the frustration of Cr moments at the boundaries of polarization domains of the SDW centered on the Mn moments.⁴

FIG. 1. Temperature dependence of the magnetic susceptibility $\chi(T)$ of $(\text{Cr}+2.7\% \text{Fe})_{1-x}\text{V}_x$ alloys, the concentration of V being shown in each panel. ZFC and FC indicate the zero-field-cooled and field-cooled state, respectively, measured and field-cooled in a field, $H=100$ Oe.

We propose that the anomaly seen in FC $\chi(T)$ curves in both CrFeV and CrCoV alloy corresponds to the onset of a local-SDW phase. Tugushev⁸ has predicted that regions of short-range SDW order will develop around a defect or impurity in a SDW host at a temperature above the bulk Néel transition to the SDW phase. We attribute the irreversibility to frustration of Cr moments that lie at the boundaries between these local-SDW regions centered on Fe moments.

The irreversibility in the paramagnetic alloy $(\text{Cr}+2.7\% \text{Fe})_{0.95}\text{V}_5$ is presumably due to its proximity to the SDW phase, though long-range order never develops in this alloy. There is negligible hysteresis in the binary alloy Cr+2.7% Fe, but the addition of only 0.07% V produces strong irreversibility [compare Figs. 1(a) and 1(b)]. The

FIG. 2. Phase diagram for $(\text{Cr}+2.7\% \text{Fe})_{1-x}\text{V}_x$ alloys showing the irreversibility limiting temperature $T_i(x)$ and the Néel temperature $T_N(x)$. The $\chi(T)$ curves for $x=1.28\%$ V are not shown in Fig. 1. The experimental data point, $T_i=0$ K, $x=10\%$ V signifies that no irreversibility (and no Néel transition) was observed in this sample down to temperature 5 K. No data point is shown for the binary alloy, Cr+2.7% Fe ($x=0\%$ V), which does not exhibit irreversibility, its Néel temperature is, $T_N=257$ K.

FIG. 3. Temperature dependence of the difference $\Delta\chi(T)$ between the FC and ZFC susceptibility relative to the value at temperature 400 K.

weak irreversibility in the binary alloy Cr+3.2% Co is also greatly enhanced by adding only 0.1% V.¹ This interesting effect, which we do not understand, is not however peculiar to V, and we see similar behavior in preliminary work on ternary alloys of Cr+2.7% Fe doped with Mo, Si, or Al.

Motivated by the geometry of the materials $\text{Na}_2\text{Ti}_2\text{As}_2\text{O}$ and $\text{Na}_2\text{Ti}_2\text{Sb}_2\text{O}$, we study a square-lattice Heisenberg antiferromagnet, with spins located at the bond centers. The largest exchange constant J couples neighboring spins in a given row or column. This leads to a mesh of isolated spin chains running along the X and Y axes. A weaker exchange constant J' couples the nearest-neighbor spins on the lattice. Classically, J' fails to fix the relative spin orientation for different chains and hence the ground state is highly degenerate. Quantum order by disorder effect is studied by spin-wave theory and numerical methods. It is shown that a four-sublattice order is favored by quantum fluctuations. However, several arguments are presented that suggest that the ground state of the system remains disordered, thus providing us with a paradigm for a two-dimensional spin liquid.

© 1998 American Institute of Physics. [S0021-8979(98)32511-6]

In recent years many new materials have been discovered which exhibit novel magnetic behavior. Various aspects of quantum magnetism, including quantum critical phenomena and existence of spin-disordered ground states with spin gaps have been observed in a variety of Cuprates, Germanates, Vanadates and other low-dimensional materials. One interesting fact that has come to light in these studies is that the geometrical arrangement of the transition metal and oxygen ions can have a dramatic impact on the underlying microscopic spin Hamiltonian and hence on the macroscopic magnetic properties of the system. For example in various cuprates, the Cu–O–Cu bond angle is crucial for determining the effective exchange constant between copper spins. Thus, strontium cuprates with certain stoichiometry behave as virtually decoupled spin ladders,¹ even though the separation of the copper spins between neighboring ladders may be smaller than their separation within a given ladder. In the CuGeO_3 (Ref. 2) and $\text{CaV}_n\text{O}_{2n+1}$,³ it is also believed that superexchange between the transition metal ions is mediated by oxygen and because of the geometry of various bond angles and occupied orbitals the second neighbor interactions are substantial compared to nearest neighbor ones.

Here, we consider a Heisenberg Hamiltonian:

$$\mathcal{H} = J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j + J' \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j, \quad (1)$$

with $J' \ll J$. The interactions are shown in Fig. 1. The exchange J couples neighboring spins in a given row or column, whereas J' is the nearest neighbor coupling between rows and columns. In the absence of J' the system consists of a square mesh of decoupled spin chains running along the X and Y axes. The motivation for studying such a model comes from the materials $\text{Na}_2\text{Ti}_2\text{Sb}_2\text{O}$ (and also $\text{Na}_2\text{Ti}_2\text{As}_2\text{O}$).^{4,5} These layered titanates consist of planes of $(\text{Ti}_2\text{Sb}_2\text{O})^{2-}$, where the oxygen atoms form a square lattice and the titanium atoms sit at the bond centers of the lattice.

The antimony atoms sit above and below the centers of the elementary squares. The titanium atoms carry spin half. It is evident from the geometry that if the dominant exchange interaction is provided by a direct overlap between the titanium orbitals, this material would behave as a nearest-neighbor Heisenberg model. If, on the other hand, the dominant interaction is mediated by oxygen orbitals, it would result in the largest interaction between neighboring spins in a given row or column, thus leading to our Eq. (1).⁶ Finally, if the dominant exchange is mediated by the p orbitals of antimony, the Hamiltonian in Eq. (1) could still be appropriate, the lattice being dual to the one shown.

We begin by studying this model in the linear spin-wave approximation. As finding the correct local spin configuration is based on energetic considerations, we expect the spin-wave theory to be at least qualitatively correct. Notice that the problem at hand has “double” degeneracy in the classical limit: it is evidently degenerate with respect to relative angle θ between quantization axes on vertical and horizontal chains, as well as with respect to relative orientation ϕ of quantization axes on the neighboring *parallel* chains. Based on the fact that Hamiltonian (1) classically has no spiral ordering, and on insight from a somewhat analogous problem of coupled planes,⁷ we restrict variation in ϕ to two possible values: $\phi=0$ (ferromagnetic ordering of neighboring parallel chains) and $\phi=\pi$ (antiferromagnetic one). This degree of freedom is then naturally represented by Ising-type discrete variable $\tau_{i,i+1}=1$ ($\phi=0$) or $\tau_{i,i+1}=0$ ($\phi=\pi$), defined for each pair of chains $(i,i+1)$. The calculations are simplified greatly by choosing quantization axes on all sites such that the ordering is ferromagnetic. This is achieved by a unitary transformation parametrized by an angle θ and a set of $(\tau_{i,i+1})$.

We now integrate out spins on the horizontal chains to find an effective Hamiltonian for the remaining spins. This is achieved by representing spins on vertical (horizontal) chains

FIG. 1. The exchange interactions J and J' in our model, shown by solid lines and broken lines, respectively.

in terms of Holstein–Primakoff bosons $a(b)$, and doing perturbation expansion in J'/J . First, nonzero contribution is of the type $J'^2 \sum_{e,e'} S_{i+e}^\alpha(a) S_{j+e'}^\beta(a) \langle S_i^\alpha(b) S_j^\beta(b) \rangle_b$, where averaging is with respect to the bare Hamiltonian of horizontal chains and S_{i+e} spins belong to vertical chains, i.e., J' acts along the $\langle i, i+e \rangle$ links. The average is nonzero when i and j belong to the same horizontal chain and $\alpha = \beta$. It is seen that effective interaction between spins on vertical chains is time-dependent, but strongest contribution comes from static ($\omega_n = 0$) part of the average. Denoting $J_\perp^\alpha(i-j) = J'^2 \langle S_i^\alpha(b) S_j^\beta(b) \rangle_b$ and $\hat{J}_\perp^\alpha(r) = J_\perp^\alpha(r-1) + J_\perp^\alpha(r)$, we find that geometry dictates the following coupling between remaining parallel chains n and m ,

$$H_{nm}^\perp = \sum_{i\alpha} \hat{J}_\perp^\alpha(n-m) S_{n,i}^\alpha (2S_{m,i}^\alpha + S_{m,i+1}^\alpha + S_{m,i-1}^\alpha). \quad (2)$$

Notice that long-range-ordered part of $\langle S_i^\alpha(b) S_j^\beta(b) \rangle_b$, if any, cancels out due to antiferromagnetic (AFM) correlations along the chains, and the effective interaction decays at least as $(n-m)^{-2}$. It is also important to realize that \hat{J}_\perp^α is anisotropic in spin space, in particular $\hat{J}_\perp^{x(z)} \sim \cos^2 \theta$. Notice that classically the system remains degenerate because $\langle 2S_{m,i}^\alpha + S_{m,i+1}^\alpha + S_{m,i-1}^\alpha \rangle = 0$. Given the fast decay of the induced interchain interaction with the distance we restrict ourselves to the strongest interaction, $\hat{J}_\perp^\alpha(1)$, between nearest chains. To find corrections to ground state energy due to this coupling, we next treat \hat{J}_\perp as a perturbation (see Ref. 7 for description of the procedure). After long algebra one finds quantum correction to the ground state energy (per chain) of M parallel chains of length N :

$$\delta E_{GS} = -\frac{1}{M} \sum_{q_y} \epsilon(q_y) C (J'/J)^4 \cos^2 \theta \sum_{i=1}^M (1 - 2\tau_{i,i+1}), \quad (3)$$

where $\epsilon(q) = 2JS|\sin q|$ is the single AFM chain dispersion in spin-wave theory, $C = (\langle S_0^x S_0^x \rangle + \langle S_0^y S_0^y \rangle)^2 / 64$, and explicit form of \hat{J}_\perp was used. Note that correction is down by $1/S$ factor, showing its quantum origin. Thus the energy is minimized by choosing all $\tau_{i,i+1} = 0$ (AFM configuration) and $\cos^2 \theta = 1$. This result agrees with well-known tendency of quantum fluctuations to favor collinear structures.^{8,9}

Having found the ground state configuration of spins, we can determine the spin-wave dispersion and calculate the reduction in sublattice magnetization due to quantum fluctuations. This reduction turns out to be divergent due to a remaining artificial degeneracy of the spin-wave spectra. Similar divergency arises in a quantum order by disorder calculations on other systems and is known to be removed by the higher-order quantum corrections to the spin-wave spectra.¹⁰ This technically difficult calculation has not been done. We would like to stress that the ground state structure found in Eq. (3) is determined by short-range spin correlations (i.e., by the correlations within the correlation length range) for which spin-wave approximation should work even if the sublattice magnetization vanishes.

Let us now take a closer look at the elementary excitations of the single chain. It is convenient to perform “staggering” of the spin configuration so that Néel ordering along the chain corresponds to the ferromagnetic one in the new representation. In this representation an elementary excitation of the chain is a domain wall (spinon) separating ferromagnetic domains of different orientation. The energy of a single domain wall is J_z . Consider now unfrustrated coupling J_\perp between nearest spins on neighboring parallel chains: however, small J_\perp is, it immediately leads to the suppression of spinons because the energy costs is proportional to $J_\perp \times (\text{length of domain})$ and diverges in the thermodynamic limit. This is an intuitive reason for the stabilization of LRO in the system of unfrustrated coupled chains.¹¹ But this is not true for our Hamiltonian (2), where each spin is coupled to the zero-spin combination of spins on the neighboring chains. Thus domain wall excitations of the single chain seems to survive in the presence of nonzero J' , hinting to the possibility of the absence of LRO.

The effect of the “mixing” interchain coupling J' can also be taken into account in the disordered phase, where the interspin interaction is isotropic. We write the partition function of the Hamiltonian (1) in the interaction representation, where independent chains are considered as unperturbed system and interchain coupling J' as a perturbation.¹² Performing trace over the horizontal chains first one finds effective interaction between spins on the vertical chains proportional to $(J'(\mathbf{k}))^2 G^{(0)}(k_x, \omega_n) S^\alpha(\mathbf{k}, \omega_n) S^\alpha(\mathbf{k}, \omega_n)$, similar to our previous spin-wave calculations. Here $G^{(0)}(k_x, \omega_n)$ is the rotationally-invariant one-dimensional spins Green’s function in Matsubara representation, and $J'(\mathbf{k}) = J' \cos(k_x/2) \cos(k_y/2)$. Decoupling spins on different chains via a Hubbard–Stratonovich transformation,¹² the 2D Green’s function of the spins on vertical chains becomes

$$G(k_x, k_y, \omega_n) = \frac{G^{(0)}(k_y, \omega_n)}{1 - (J'(\mathbf{k}))^2 G^{(0)}(k_x, \omega_n) G^{(0)}(k_y, \omega_n)}. \quad (4)$$

The known form of $G^{(0)}(k_x, \omega_n)$ ¹³ implies that (i) the singularity at $\mathbf{k}_0 = (\pi, \pi)$ remains unchanged because $J'(\mathbf{k}_0) = 0$, (ii) the uniform susceptibility is $\chi = \chi_0 / [1 - (\chi_0 J')^2]$, where $\chi_0 = 1/(\pi^2 J)$ is susceptibility of single chain, and (iii) interchain coupling comes into play below $T^* \sim J'$. Within this approximation, the two-dimensional system remains in the disordered critical state at $T = 0$, and in the quantum-critical

one at finite temperatures. This result should also be viewed with some caution due to the large degeneracies in the underlying problem.

We now turn to numerical studies. Because of multiple energy scales, the development of short-range order at high temperatures is not necessarily indicative of the order for $T \sim J' \ll J$. Thus we need to study the ordering tendency directly at low temperatures. As $J'/J \ll 1$, the coupling between the local order parameters on the neighboring parallel chains can be gotten by perturbation theory. We study the following correlation function between neighboring vertical chains:

$$c_{12} = \left\langle \sum_i (-1)^i \mathbf{S}_{1,i} \cdot \sum_j (-1)^j \mathbf{S}_{2,j} \right\rangle, \quad (5)$$

here $\mathbf{S}_{1,i}$ represents spins on first vertical chain and $\mathbf{S}_{2,i}$ represents spins on second vertical chain. A value of $c_{12} > 0$ would imply ferromagnetic ordering whereas $c_{12} < 0$ would imply antiferromagnetic ordering. The leading order contribution to c_{12} requires the interactions to be mediated by at least two horizontal chains. To make the perturbation theory numerically tractable, we confine ourselves to finite chains along vertical and horizontal directions (with periodic boundary conditions). For four spins in each of the chains, we can carry out perturbation theory using series expansion methods.¹⁴ We find that $c_{12} \approx -9 \times 10^{-6} (J'/J)^6$, which is negative confirming the tendency of the parallel chains to align antiferromagnetically. We have also used Lanczos methods to calculate this correlation function with up to 6 spins in each chain for $|J'/J| \leq 0.3$. In all cases the coupling remains antiferromagnetic and very weak. For the six-spin system, c_{12} appears to scale as $(J'/J)^4$ as expected from general arguments and spin-wave theory presented earlier. Diagonalization of a 32-site system is in progress.

Assuming the local ordering pattern obtained in spin-wave theory, we can now investigate the question of long-range order by an Ising expansion for our original Hamiltonian. We write the Hamiltonian as $\mathcal{H}(\lambda) = H_0 + \lambda H_1$, where H_0 consists of an Ising Hamiltonian, whose two ground states are ordered in the four-sublattice pattern and $H_1 = \mathcal{H} - H_0$, with \mathcal{H} being the full Hamiltonian in Eq. (1). We develop expansions for the sublattice magnetization in terms of the expansion parameter λ . If the system has long-range order, the expansion should converge up to $\lambda = 1$, whereas if it is disordered there should be a critical point at $\lambda < 1$. Without explicit calculations, we can make the following observation: because of the cancellation of the effective field from one chain to another, the purely one-dimensional graphs remain unaffected by the coupling between the chains. We know that these add up to zero sublattice magnetization at the Heisenberg point. The effects of the other graphs is to further reduce order, thus moving the Heisenberg system into a quantum disordered phase. We have carried out these expansions to order λ^8 for a range of J'/J values. The analysis suggests critical values less than unity, implying a disordered ground state for the Heisenberg limit.

Additional insight can be gained by studying the $J' \gg J$ limit of the model, where the Néel state on 45° rotated lattice is stabilized by the J' interaction. As J increases from zero, quantum fluctuations grow stronger and at $(J/J')_{\text{crit}} = 0.76$ (within linear spin-wave approximation) finally destroy long-range order, analogous to $J_1 - J_2$ model.⁸ That these two systems are very similar is also supported by the fact that the critical value of frustrating interaction J quoted above is exactly twice the corresponding critical value of $J_1 - J_2$ model. Given this analogy, we speculate that disordered phase at $J/J' \geq 0.76$ is a spontaneously dimerized one,^{14,15} with vertical and horizontal chains formed by the exchange J being in the valence-bond-type state. However, extensions of these results to $J/J' > 1$ is problematic as at $J = J'$ this system classically has a finite ground state entropy¹⁶ and may change character at that point. Clearly, more work is needed to understand the nature of the disordered phase. It is interesting to ask what will happen upon introducing of a mobile charge carriers into the chains. There are apparent similarities of this problem with a recent study of a square mesh of conducting horizontal and vertical stripes.¹⁷

In conclusion, we have identified a new frustrated layered Heisenberg model, which could have a two-dimensional spin-liquid ground state. The magnetic properties of the materials $\text{Na}_2\text{Ti}_2\text{As}_2\text{O}$ and $\text{Na}_2\text{Ti}_2\text{Sb}_2\text{O}$ maybe represented by such a model.

The authors thank S. Kauzlarich and A. Axtell for bringing these materials to our attention, and I. Affleck, A. Chubukov, S. Sachdev, and M. Zhitomirsky for discussions. Calculation of the energy barriers in strongly interacting many-particle systems

D. V. Berkov

INNOVENT e.V., Göschwitzer str. 22, D-07745, Jena, Germany

A numerical method which allows the evaluation of the energy barrier height between any two metastable states in a many-particle system with continuous degrees of freedom and arbitrary interparticle interaction is presented. The method uses the minimization of the Onsager–Machlup action corresponding to the given path between the two states. The path which minimizes this action is supposed to be the optimal path between the states under consideration and the height of the energy barrier separating these states is determined as the energy barrier along this optimal path. Test results for a simple two-dimensional potential (where the optimal path can easily be visualized) and for a dipolar glass are presented. © 1998 American Institute of Physics.
[S0021-8979(98)32611-0]

Evaluation of the energy (and free energy) barriers between metastable states in interacting many-particle systems is one of the most challenging problems in various areas of physics,¹ in particular, in the condensed matter physics of disordered systems with frustration like spin glasses.^{2,3}

At the present time we lack general methods for the evaluation of these barrier heights, except, maybe, direct Monte Carlo simulations of the system escape over such barriers which are based on the Langevin equations^{1,4,5} and can be applied only if the barrier height ΔE is comparable with the temperature T . In this contribution we would like to propose a numerical method which in its initial form is suitable for the energy barrier evaluation of arbitrary height in any classical interacting many particle system with continuous degrees of freedom, e.g., systems of “usual” classical particles, dipolar and RKKI spin glasses, Heisenberg (but not Ising!) models.

Main idea. Since the work of Onsager and Machlup,⁶ it is well known (see also Ref. 7) that for a system of N classical particles which motion can be described by coordinates $\mathbf{x}=(x_1, \dots, x_N)$ and velocities $\dot{\mathbf{x}}$ and which interaction energy $V(\mathbf{x})$ depends on their coordinates only the probability to observe a given trajectory $\mathbf{x}(t)$ for the transition between the two states A and B during the time t_f [$\mathbf{x}_A(0) \rightarrow \mathbf{x}_B(t_f)$] is given by

$$P[\mathbf{x}(t)] \approx J[\mathbf{x}] \exp \left[-\frac{S[\mathbf{x}(t)]}{4D} \right], \quad (1)$$

where the action $S[\mathbf{x}(t)]$ is defined as

$$S[\mathbf{x}(t), t_f] = \int_0^{t_f} dt \sum_i \left(\frac{dx_i}{dt} + \frac{\partial V(\mathbf{x})}{\partial x_i} \right)^2. \quad (2)$$

The form of the action (2) is the direct consequence of (i) the Langevin equations of the particle motion under the influence of the deterministic and random thermal forces (neglecting inertial terms) and (ii) the assumption that these thermal forces can be considered as independent Gaussian random quantities with zero correlation time. The Jacobian $J[\mathbf{x}]$ accounts for the variable transformation from the system coordinates to the thermal forces and the coefficient D in

the exponent of (1) characterizes the thermal noise power and hence is proportional to the system temperature: $D \sim T$.

In principle, the statement (1) solves any problem related to the transition between A and B , because the total transition probability $P_{\text{tot}}(A \rightarrow B)$ is then given by the integral of (1) over all paths $\mathbf{x}(t)$ and transition times t_f . Unfortunately, the evaluation of the corresponding path integral is not possible for any interacting system of real interest, which is probably the reason why the idea outlined above was not used in real calculations except some one-dimensional (1D) problems.^{8,9}

However, it can be seen from (1) that in the low temperature limit ($D \rightarrow 0$ and hence $T \rightarrow 0$) the only significant contribution to $P[\mathbf{x}(t)]$ comes from the paths near the trajectory which minimizes the action $S[\mathbf{x}(t)]$; it is called an “optimal” path $\mathbf{x}_{\text{opt}}(t)$. In this case the energy barrier for the transition $A \rightarrow B$ can be found as the barrier along this trajectory: $\Delta E(A \rightarrow B) = E_{\text{max}}(\mathbf{x}_{\text{opt}}) - E_A$. So the “only” problem left is the minimization of the action functional $S(\mathbf{x})$.

The easiest way to perform this minimization is the approximation of the integral (2) by some numerical quadrature formula and the subsequent minimization of the many-variable function obtained this way. Approximating (2) by the simplest quadrature, we obtain

$$S_d(\mathbf{x}) = \Delta t \sum_{i,k} \left[\frac{x_i^{k+1} - x_i^k}{\Delta t} + \frac{1}{2} \left(\frac{\partial V(\mathbf{x})}{\partial x_i^{k+1}} + \frac{\partial V(\mathbf{x})}{\partial x_i^k} \right) \right]^2, \quad (3)$$

where $\Delta t = t_f/K$, K is the number of time slices used, x_i^k is the coordinate of the i th particle at the time $t_k = k\Delta t$. The problem of the determination of the time slice number will be addressed elsewhere.¹⁰ Minimization of $S_d(\mathbf{x})$ as a function of $N \cdot K$ variables x_i^k provides a discrete representation of the optimal path which can be used to calculate the corresponding energy barrier.

A simple test example. The result of the simplest possible test of the method, calculation of an optimal trajectory for a transition of a particle in a 2D space (x_1, x_2) between the two local minima of the potential

$$V(\mathbf{x}) = \sum_j U_j \left[1 + \left(\frac{\mathbf{x} - \mathbf{r}_j}{\Delta_j} \right)^2 \right]^{-1} \quad (4)$$

FIG. 1. Optimal trajectory (white line) for the particle transition between the two minima M_1 and M_2 .

is shown in Fig. 1. The energy surface used possesses two peaks P_1 and P_2 ($U_j > 0$) and two holes M_1 and M_2 ($U_j < 0$). The starting trajectory for the minimization process was a straight line $M_1 - M_2$. The final trajectory shown in Fig. 1 clearly passes through a saddle point providing the correct value of the energy barrier separating the minima M_1 and M_2 (a "true" optimal trajectory).

In this test case the optimal trajectory could be easily found due to a simple energy landscape. For a many-particle system, the search for a true optimal path between the two energy minima by the minimization of the action (2) [or (3)] is much more difficult, because this action has many local minima. Namely, any trajectory which proceeds along the gradient lines of the energy surface (i.e., for which $\dot{x}_i = \pm \partial V\{x\}/\partial x_i$) provides a local extremum to the action (2), see Ref. 9 for the proof in the 1D case.

For the energy surface presented in Fig. 1, this means, e.g., that the trajectory climbing along the gradient lines from M_1 up to P_1 and then going downhill from P_1 to M_2 also provides a local minimum to the action (2), and obviously gives a wrong value of the energy barrier (a "false" optimal trajectory). It is easy to construct an example where even the values of the action corresponding to the true and false optimal paths would be the same (just consider a system of two noninteracting particles each moving in a 1D double-well potential). For this reason, an additional analysis of the found optimal trajectories is necessary, so we developed an algorithm to distinguish between the true and false action minima (trajectories passing through the saddle points and climbing over the local maxima); due to the lack of space details of this algorithm will be described elsewhere.¹⁰ Here we would like to present only its main idea: for many-particle systems with complicate energy landscape, we expect that *many different* local energy minima can be achieved when we minimize the system energy starting from any en-

ergy maximum and moving in different directions (in contrast to Fig. 1 where only two minima exist). For this reason, we have tried to find out which local energy minima can be found starting from various points scattered randomly in the vicinity of the trajectory point P_E with the largest energy. For a true optimal trajectory, P_E is a saddle point for the transition $M_1 \rightarrow M_2$ and the energy minimization starting P_E (or sufficiently close points) would bring us either to M_1 or to M_2 . For a false optimal trajectory, P_E represents an energy maximum so that minimizing the system energy starting from P_E we would (with the probability rapidly growing with the particle number) discover other local minima different from both M_1 and M_2 . This would indicate that P_E is a maximum rather than a saddle point and that the corresponding optimal trajectory is a false one.

Implementation of the method for a system of magnetic particles. Let us consider, e.g., a system of small identical single-domain ferromagnetic particles (fixed in a nonmagnetic matrix) each having the volume V and the saturation magnetization M_s and carrying the magnetic moment \mathbf{m}_i of a constant magnitude $m_i = VM_s$. The magnetization state of such a system can be defined most conveniently using the spherical angles (θ_i, ϕ_i) characterizing the orientation of the i th magnetic moment. Below we denote the set of these spherical coordinates for all particles as Ω .

The action $S[\Omega(t)]$ corresponding to the transition $\Omega_A \rightarrow \Omega_B$ between the two given metastable states A and B of the system can be derived from the Landau-Lifshitz-Gilbert equations of motion for magnetic moments in the presence of thermal fluctuations¹¹ exactly as the action (2) is derived from the Langevin equations of motion for usual particles.^{6,9} The result is (if the precession term can be neglected)

$$S[\Omega(t)] = \int_0^{t_f} dt \sum_i \left[\left(\frac{d\theta_i}{dt} + \frac{\partial E\{\Omega\}}{\partial \theta_i} \right)^2 + \left(\sin \theta_i \frac{d\phi_i}{dt} + \frac{1}{\sin \theta_i} \frac{\partial E\{\Omega\}}{\partial \phi_i} \right)^2 \right]. \quad (5)$$

Minimization of this functional in the Ω space gives the "optimal" path which can provide information about the energy barrier between the states Ω_A and Ω_B exactly as explained above.

The method was applied to a system of magnetic particles having the "easy axis" magnetic anisotropy with the energy $E_{an} = 0.5\beta M_s^2 V \sin^2 \psi$, where $\beta(>0)$ is the reduced anisotropy constant and ψ is the angle between \mathbf{m} and the easy axis direction \mathbf{n} . Without the external field (this was always the case for the results reported below) a single such particle has two equivalent equilibrium magnetization states (along the two opposite directions of the anisotropy axis) separated by the reduced energy barrier $\epsilon \equiv E/(M_s^2 V) = \beta/2$. The barrier found by our algorithm for a single such particle or for a system of noninteracting particles with different anisotropy constants agreed with this value within the numerical accuracy. The test on a system of noninteracting particles was necessary to ensure that the algorithm discriminating between the false and true local minima of the action works properly.

FIG. 2. Energy barrier distributions found by our algorithm for the system of $N=128$ dipolarly interacting magnetic particles with the uniaxial anisotropy ($\beta=2.0$) for various particle volume fractions c as shown in the figure.

Next we considered a system of $N=128$ dipolarly interacting particles with equal anisotropies $\beta_0=2.0$ which were placed randomly (but nonoverlapping) in the cubic volume; periodic boundary conditions were assumed. The dependence of the energy barrier distribution on the particle volume concentration c was studied. To obtain the distribution density of energy barriers we have generated a number of (meta)stable states starting from various initial moment orientations and then minimized the actions (5) corresponding to the transitions between various pairs of these states. Typically for each histogram shown in Fig. 2 and Fig. 3 several hundred energy barriers were calculated.

Results of our simulations are shown in Fig. 2. As it should be, for the lowest concentration ($\eta=0.001$) almost all barriers are nearly equal to the single-particle barrier $\epsilon = \beta_0/2 = 1.0$ because for this concentration the interaction effects are almost negligible. Note, however, a few barriers well below this value which occur due to a strong interaction of particles positioned by chance very close to each other. Already for the next (still quite low) volume concentration $\eta=0.01$, a considerable amount of barriers with another (mostly lower) values occur, because a fraction of closely positioned particles increased. For the system with the moderate ($c=0.08$) and high ($c=0.24$) concentrations, the collective interaction effects lead to a qualitatively different energy barrier distribution strongly shifted to the lower energies.

Another example of such a transition from the single particle to the collective behaviour is presented in Fig. 3, where results of our simulations for a system of $N=128$ particles with the particle volume concentration $c=0.04$ and different single-particle anisotropy constants are shown (note

FIG. 3. The same as in Fig. 2 for systems of particles with the concentration $c=0.04$ and various anisotropy constants β as shown in the figure.

the logarithmic scale of the energy axis). It can be seen that for the smallest anisotropy considered ($\beta=0.1$) collective effects clearly dominate, whereby all barriers found in the system with the largest anisotropy value ($\beta=10.0$) lie in the vicinity of the single-particle energy barrier $\epsilon = \beta/2 = 5.0$.

Due to the limited paper length we cannot discuss the relation between our results and experimental data, e.g., for magnetic viscosity^{12,13} or ac susceptibility of ferrofluids.¹⁴ We only mention that care should be taken by establishing such a relation because (i) all experiments were performed at finite (and even not at low) temperatures so that the density of free energy barriers is required for their interpretation, (ii) transitions over different barriers lead to different moment changes which is essential for the calculation of both magnetic susceptibility and magnetic viscosity. Clearly further investigations are necessary.

The dynamics of dipolarly coupled magnetic moment systems representing sets of microwires has been simulated in the cases of (i) moments coupled through first-neighbors dipolar interactions and in that of (ii) moments coupled through exact many-body dipolar ones. Our results show that, in the case of the small size systems and independently from their parity, the dynamics is based either on localized excitations (of the antiferromagnetic domain wall-like type) or in collective modes depending on the occurrence of either short- or long-range dipolar interactions, respectively. When large size systems are considered the dynamics is based on localized interactions independently of the parity and the type of the present interactions. © 1998 American Institute of Physics. [S0021-8979(98)32711-5]

It has been shown that sets of glass-coated microwires, produced by the Taylor technique,¹ have an interesting dynamics characterized by the occurrence of multistable behavior² which makes them especially interesting in order to develop magnetic field sensors.³ Our purpose here is to analyze, in terms of a simple model, the dynamics of the magnetization reversal of sets of microwires having different size, parity, and range of dipolar coupling. Our model system corresponds to equally spaced individual microwires disposed in a ring. In real microwires, the field-induced magnetic moment reversal proceeds through a nucleation-propagation sequence with associated local moment structures involving only a small part of the total volume of the wire.¹ Therefore, a fine microwire discretization would be necessary in order to describe that reversal in a rigorous manner. Nevertheless, and since the propagation of the initially reversed nucleus is very rapid¹ and considering the fact that the wires have a length-to-diameter ratio of the order 10^3 , in what follows we will represent their magnetic state by that of a single magnetic moment with only two possible orientations. We will also assume that those magnetic moments (as the applied magnetic field) always point perpendicularly to the ring plane. To allow that thermal fluctuations could play a significant role in the demagnetization process, we have chosen a magnitude for the magnetic moments forming the system of 10^{-14} A m². The total system energy includes dipolar and Zeeman terms and is written as

$$E = \mu_0 M_s^2 \sum_{i,j=1}^N \frac{1}{d_{ij}^3} (\vec{m}_i \vec{m}_j) - \mu_0 M_s \sum_{i=1}^N \vec{m}_i (\vec{H} - \vec{H}_c),$$

where $m_i = \pm 1$, d_{ij} is the intermoment distance corresponding to the i th and j th sites (the distance between neighboring microwires is $d = 2 \times 10^{-5}$ m), $\mu_0 H$ is the applied magnetic field and $\mu_0 H_c = 5 \times 10^{-6}$ T represents the microwire coercivity which we phenomenologically introduce as a field parallel to the applied one for the demagnetizing branch of the hysteresis loop and antiparallel to it for the remagnetizing

one. We have considered two different interactions schemes: (i) nearest-neighbors interactions (in this case $j = i \pm 1$, $d_{ij} = d$ and the model coincided with the antiferromagnetic Ising) and (ii) exact, long-range, many-body interactions. When the external applied field was varied in small steps ($\mu_0 \Delta h = 5 \times 10^{-8}$ T), the dynamics of the system was followed by means of a Monte Carlo algorithm implemented with Metropolis dynamics in a canonical ensemble. The temperature fluctuations were introduced as random moment reversals. These reversals were accepted either in the case when they resulted in system internal energy decrease or when a system energy increase was consistent with the Boltzmann distribution function. Figures 1(a) and 1(b) show the hysteresis loops evaluated in two small size systems having first-neighbors interactions and even (8) and odd number (9) of moments, respectively. In the case of the 8 moments system, a state of zero component (measured along the applied field direction) of the total magnetic moment, corresponding to the (antiferromagnetic) ground state of the dipolar interactions, can be achieved. In contrast with this, in the case of

FIG. 1. (a) Hysteresis loop evaluated in (a) 8 moment and (b) 9 moment systems (first-neighbors coupling, $T = 50$ K).

FIG. 2. Field dependence of the temporal correlations in systems having 8 and 9 moments coupled by many-body and first-neighbors interactions (inset) ($T=100$ K, $\tau=20$ MCS measured after a thermalization stage of 20 MCS).

FIG. 3. Demagnetization branches of the hysteresis loops corresponding to systems formed by 21 moments coupled through first-neighbors and long-range interactions ($T=100$ K, average over 10^3 temperature realizations).

the 9 moments system that zero component state cannot be achieved due to the topological frustration of one of the moments in the system. That frustration is associated to the twofold total moment degeneracy of the ground state of the dipolar interactions and is made evident by the four different states that can be stabilized, in different field ranges, in this case. The dynamics of small size systems with only first-neighbors interactions is illustrated as inset in Fig. 2, where we present data corresponding to the applied field dependence of the quantity $\langle m_i(t)m_i(t+\tau) \rangle_{i,t,T}$ giving the configurational, thermal and time (measured in number of MCS) average of the system correlations after a time. As it is clear from the figure both systems are perfectly autocorrelated at all the field values with the only exception of those corresponding to the transitions between the stable states. This result suggests that these transitions involve localized excitations which should correspond to the creation or annihilation of pairs of antiparallel local moments (the exception to this should be the reversal of the frustrated moment in the case of the odd number of moments systems, which could involve three moments). Evaluation of $\langle m_i(t)m_i(t+\tau) \rangle_{i,t,T}$ in systems having 8 and 9 moments and many-body dipolar interactions (see Fig. 2) revealed that in this case the system was more frustrated than when only the first-neighbor interactions are present. In a larger size system with many-body dipolar interactions, the dynamics is of the collective type. To discuss that point let us assume that the system is saturated upwards and submitted to a demagnetizing applied field slightly lower than that corresponding (in systems with only first-neighbors interactions) to the transition from the saturated state to the ground state of the dipolar coupling. If, due to the thermal fluctuations the i th moment reverses, its reversal induces changes in the local field of the $(i \pm 1)$ th moments. If the acting dipolar interactions are of the nearest-neighbors type, the dipolar field at the $(i \pm 1)$ th moments will be zero since the $(i \pm 2)$ th and the i th moments are antiparallel. Differently, if the moments are coupled through long-range interactions the dipolar field at the $(i \pm 1)$ th moments reinforces the applied one: the first-neighbors contribution to the local field is still zero but the second neighbors one (which dominates the total dipolar field) is of the demag-

netizing type (both second neighbors still point along the initial saturation direction). Thus, the reversal of the $(i \pm 1)$ th moments is favored in the case of the long-range interactions with respect to that of first neighbors ones. Once the reversal of the $(i \pm 1)$ th moments is accomplished the antiparallel alignment with the field of the i th moment is, for similar reasons, favored, which allows to achieve locally the antiferromagnetic magnetic moment configuration. Also, and more generally, in a system with many-body interactions, the first-neighbor moments of those limiting a region with antiparallel moment configuration will always tend to flip due to the demagnetizing dipolar field created by their second neighbors. In conclusion, the presence of long-range dipolar interactions favors a system size large avalanche-like reversal process. Our point is clearly illustrated in Fig. 3 where we compare the demagnetizing branches of the hysteresis loops evaluated in two 21-moment systems having first-neighbors and many-body interactions, respectively. From these results, it is clear that the nucleation of the antiferromagnetic state takes place at a measurably smaller field in the case of the system undergoing many-body interactions. Figure 4 shows the variation of the demagnetization branch of the hysteresis loop with the number of moments integrating the system.

FIG. 4. Demagnetization branches of the hysteresis loops corresponding to systems formed by different (even) number of moments coupled through long-range interactions ($T=10$ K, average over 200 temperature realizations). The insets show the probability of occurrence (in two different systems) of spinons of different sizes.

FIG. 5. Field dependence of the temporal correlations in a system having 52 moments coupled by first neighbors ($\tau=10$ MCS measured after a thermalization stage of 20 MCS).

Our data show the occurrence, for sufficiently large system sizes, of intermediate states in the moment reversal process as those observed in the case of the odd number of moments systems. These states are characterized by the presence of uncompensated moments (antiferromagnetic domain wall-like structures or spinons).⁴ The insets in the figure present, for the case of the systems having 24 and 52 moments, histograms showing the probability of occurrence of a given number of antiferromagnetic domain wall structures at a field of -4.5×10^{-6} T. In Fig. 5 we have plotted the temperature and field dependence of the $\langle m_i(t) m_i(t+\tau) \rangle_{i,t,T}$ correlations evaluated for a system having 52 moments (first-neighbors interactions). Our results (indistinguishable from those obtained in a system with 51 moments) clearly evidence that the dynamics of these large systems is linked to localized excitations. Finally, in Fig. 6 we show the time evolution of the $\langle m_i(t) m_i(t+\tau) \rangle_{i,t,T}$ correlations of two systems formed by 51 moments and having first-neighbors (inset) and many-body interactions, respectively. If the moments are coupled through many-body interactions it is possible to observe, at an intermediate temperature range, that the correlations oscillate. These oscillations are related to the site degeneracy, since they are produced by the continuous displacement of the spinons present in the system. Comparison of the behavior of the two considered systems reveals that at sufficiently low temperatures both systems are perfectly time autocorrelated.

FIG. 6. Constant field (-4.8×10^{-6} T) time dependence of the temporal correlations evaluated in a system having 51 moments coupled through long-range interactions. The inset shows the time dependence of the same quantity in a system of 51 moments coupled through first-neighbor interactions.

lated. Nevertheless, the increase of the temperature produce different effects on the correlation depending on the type of interactions. For instance, at 1000 K, the system with first-neighbors interactions is still perfectly time autocorrelated whereas that having many-body interactions evidences that the correlation is lost after a short time. This result clearly indicates that, upon the introduction of the long-range dipolar coupling, it is much easier to achieve excited states of the dipolar interactions. To conclude we should say that, independently from the parity of the system (and therefore from the occurrence of frustration and from that of topological degeneracy), in the case of small size systems, the dynamics seems to be collective if many-body dipolar interactions are present and related to localized excitations if the moments are coupled through short-range dipolar fields. The dynamics of the larger system is always linked to localized excitations since, for the considered geometry, the increase of the total number of magnetic moments results in the increase of the distance between different regions of the system (the increase in size is thus associated to a decrease of the magnitude of the long-range interactions).

Domain models for aging in spin glasses

Derek Walton

Department of Physics and Astronomy, McMaster University, Hamilton, Ontario, Canada

A simple domain growth model is shown to account for aging in spin glasses. It accounts quantitatively for the change in glass temperature with frequency. It is shown that percolation clusters present in disordered systems are responsible for the peak in $\partial M / \partial \ln t$, where M is the magnetization, and t is the time. © 1998 American Institute of Physics. [S0021-8979(98)27611-0]

INTRODUCTION

The magnetization of a spin-glass which has been cooled in zero field displays aging effects below the glass temperature, i.e. it depends on the time elapsed before application of the magnetic field. The derivative of the magnetization with respect to $\ln t$, divided by the field, called S , shows a similar structure in all systems investigated.^{1,2} Characteristics are a peak at a time close to the waiting time, t_w , and a difference in the initial value of S which depends on the waiting time, with longer waiting times resulting in lower initial values of S . Longer waiting times also result in lower initial values of the magnetization.

At present two seemingly quite different explanations are advanced: The Parisi³ solution of the Sherrington-Kirkpatrick Hamiltonian⁴ has inspired a model in which metastable states are hierarchically organized in phase space. Aging is the result of the system overcoming barriers and populating additional states.⁵ The other considers aging to result from the growth of droplets⁶ or domains of correlated spins.^{7,8} Both approaches lead to spin relaxation times which slow as $\ln t$; so the differences between them may be more conceptual than real.

Qualitative agreement with experiment, in the sense that calculated curves are more or less similar to measured data, has been demonstrated by many authors, but quantitative agreement is another matter. The hierarchical model has been shown⁵ to yield a substantially correct position for the peak in S , but a relatively large initial value of S , on the order of half the peak value, which depends on the waiting time, is not reproduced. It will be shown that a domain model gives not only the correct peak position, but the other details as well.

Following Fisher and Huse,⁶ FH, consider an Ising spin glass with nearest neighbor interactions on a d dimensional lattice. The Hamiltonian is

$$\mathcal{H} = - \sum_{\langle i,j \rangle} J S_i S_j - H \sum_i S_i, \quad (1)$$

where the spins, $S_i = \pm 1$, J is the nearest neighbor exchange, and H is a uniform magnetic field.

In FH the characteristic length scale of domains grows as

$$R \sim \left[\frac{T \ln(t/\tau)}{\Delta(T)} \right]^{1/\psi} \quad (2)$$

where τ is a microscopic time, and ψ is the barrier exponent, $1 \geq \psi > \frac{1}{2}$. Δ sets the overall free energy scale of the barriers; for $T \ll T_g$ it is $\sim J$.

If the microscopic nature of the spin relaxation is considered it is clear that the relaxation of a spin reduces its constraint on its neighbors one of which can then relax, reducing the constraint on its neighbors, and so on along a sequence of spins. It is clear that the domain size cannot exceed the size of such a sequence. If the domain size is proportional to the distance between the first and last spins in the sequence Walton,⁸ W , derives

$$R \sim \left[\frac{\ln(t/\tau)}{\ln p} \right]^\beta, \quad (3)$$

where p is the number of equilibrium positions for S , in the Ising model $p=2$ (the Ising model will be used in the remainder of this paper), and β relates the number of spins in a sequence of relaxed spins,

$$n = \frac{\ln(t/\tau)}{\ln p},$$

to R , the average distance between the first and last spins in the sequence, i.e., $R \sim n^\beta$. If \hat{d} is the spreading dimension,⁹ and D the fractal dimension, the number of spins in the domain is R^D , and $\beta \sim \hat{d}/D$. In 3 dimensions $\hat{d}=1.83$, and $D=2.5$,⁹ yielding $\beta=0.732$. On the other hand, numerical simulations give $\beta \approx 0.88$.¹⁰

Making an effective medium approximation¹⁰ for the energy barrier to spin reversal, $\tau \sim \omega_0 e^{-(E/T)}$, where ω_0 is a fundamental attempt frequency, and E is the effective medium energy barrier in temperature units.

Both expressions are of the form

$$R = A [\ln(t/\tau)]^a = A \ln^a(t/\tau), \quad (4)$$

where a is now a parameter, and A is temperature dependent in FH, but not in W . FH require $1 \leq a < 2$, and in $W a < 1$.

It is clear that if t is measured from the end of a waiting time t_w

$$R \propto \ln^a \left(\frac{t_w + t}{\tau} \right) \equiv \ln^a(g + k). \quad (5)$$

THE GLASS TRANSITION TEMPERATURE, T_g

If after cooling to a low temperature a small field is applied, an increase in moment occurs because domains are able to grow, and R is able to increase. An increase in tem-

perature allows R to increase faster, and the moment increases as the temperature is raised. Eventually nucleation of new domains in the interior of existing domains limits their size. After a time $t_l < \tau_n$ the domain volume is $R^D = A^D \ln^b(t_l/\tau)$, where $b = aD$. If there N spins, and the difference in energy between the two spin orientations is V , $n_\tau = Ne^{-(V/T)}$ spins will be reversed, and can nucleate new domains. Using the criterion that the maximum domain size is one that contains one reversed spin. The maximum susceptibility will occur when $R^D e^{(-V/T)} \sim 1$, leading to

$$T_g = \frac{V}{D \ln A + b \ln(\ln \omega_0 t_l - (E_l/T_g))}. \quad (6)$$

T_g can be obtained from this rather inconvenient expression.

THE PEAK IN $S = \partial M / H \partial \ln t$

Domain boundary motion takes place by relaxation of spins on the boundary. This will occur preferentially at spins with equal numbers of neighbors on both sides of the boundary so that the constraint imposed by the interaction with the neighbors is removed. Thus relaxation of spins on the boundary can be considered to be a process of continual nucleation of new domains at spins. Therefore, the boundary of a domain of scale R can be viewed as consisting of smaller domains of scale $\ln^a(t'/\tau)$, where $t' < (t + t_w)$, resulting in a self-similar fractal surface for the domain boundary, and the area of the boundary will be R^{d_s} , where $d_s > d - 1$.⁶ Thus after a time t has elapsed it should be possible to identify volumes on the boundary on all scales $\ln^a(t')$ where $t' \leq t$. In zero field this picture becomes somewhat academic since growth proceeds at equal rates for both spin orientations. However, in a magnetic field this is no longer the case, and the volumes of domains nucleated after the field is applied is different for the two spin orientations.

In a magnetic field H , $\tau \sim \omega_0 e^{-(Q \pm \mu H)/(T)} = \tau_0 e^{\pm h}$, where $h = (\mu H)/(T)$. If t is measured from the time the field was first applied

$$R^\pm \propto \ln^a(g + ke^{\pm h}) \quad (7)$$

and the new domain volumes are different.

The spins can be expected to lie on a percolation structure which can be viewed as a collection of clusters.¹¹ Below the percolation limit the clusters are isolated from each other. Above it the infinite cluster can be viewed as an assembly of clusters, some of which are connected, this is the "blobs" and "links" model.¹² For concentrations above the percolation threshold the cluster size distribution can be approximated by $s^\theta e^{-Cs^\nu}$,¹¹ where s is the number of spins in the cluster, and C is a constant on the order of the number of spins in the average cluster. In 3d, above the percolation threshold $\theta \sim \frac{1}{3}$, and $\nu = \frac{2}{3}$, below, $\theta \sim -\frac{3}{2}$ and $\nu = 1$.

Clusters smaller than $\ln^a g$ will be single domain. After the field is applied domain growth will take place in the larger clusters at different rates for the two spin orientations. As a consequence clusters with $\ln^a g < R^\pm \leq \ln^a(g + ke^{\pm h})$ will become single domain. The difference between their vol-

FIG. 1. The points are experimental values of $S = (1/H)(\partial M / \partial \ln t)$ in units of $0.01M/H$ for $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_2$ for two different waiting times, 10^2 s, and 10^4 s from Svedlindh *et al.*¹³ The solid lines are calculated.

umes will contribute to the moment. The number of spins in the domain is $\sim R^D$ and this contribution to the moment is

$$\delta M_d \propto \int_{[\ln^a g]^D}^{[\ln^a(g+ke^h)]^D} s^{1+\theta} e^{-Cs^\nu} - \int_{[\ln^a g]^D}^{[\ln^a(g+ke^{-h})]^D} s^{1+\theta} e^{-Cs^\nu}. \quad (8)$$

Clusters smaller than $[\ln^a g]^D$ will have become single domain during the waiting period before the field was applied. Their moments cancel since the temperature is below T_g , and nucleation of new domains in the interior of clusters can be neglected.

A second contribution will come from nucleation of new domains after the field is applied. The moment produced will just be proportional to the difference in volume of the new domains. Domains will nucleate most easily on the domain boundary. Nucleation in the interior of existing domains will be unimportant at temperatures below T_g , and will be neglected, thus, with $b = aD$

$$\delta m_n \propto \ln^b(ke^h) - \ln^b(ke^{-h}) = 2hb \ln^{b-1} k. \quad (9)$$

This contribution to the sample moment will be proportional to the total domain boundary area: If the domain contains $n^b = \ln^b(g+k)$ spins, and has area R^{d_s} or n^c , where $c = ad_s$, a cluster of s spins will contain $\sim s/n^b$ domains, whose total area can be roughly estimated as $\sim (s/n^b)n^c$, and

$$\begin{aligned} \delta M_n &\propto h \ln^{b-1} k \left[\int_{n^b}^{\infty} \frac{s^{1+\theta}}{n^{b-c}} e^{-Cs^\nu} \right] \\ &= h \frac{\ln^{b-1} k}{\Gamma(\alpha) \ln^{b-c}(g+k)} \Gamma(\alpha, Cn^{\nu b}), \end{aligned} \quad (10)$$

where $\alpha = (2 + \theta)/(\nu)$, $\Gamma(\alpha, x)$ is the incomplete gamma function, and $\Gamma(\alpha)$ is the gamma function.

We wish to calculate $S = S_d + S_n = \partial / h \partial \ln t (\delta M_d + \delta M_n)$.

Differentiating the integrals in Eq. (8), expanding, and only retaining terms in h

$$S_d \propto \frac{kg}{(g+k)^2} \left\{ 1 + \frac{k}{g \ln(g+k)} [(2+\theta)b-1 - C\nu b \times \ln^{\nu b}(g+k)] \right\} \frac{\ln^{(2+\theta)b-1}(g+k)}{e^{C \ln^{\nu b}(g+k)}}. \quad (11)$$

Differentiating (10), and neglecting terms in h^2 ,

$$S_n \propto \frac{\ln^{b-2} k}{\ln^{b-c}(g+k)} \left\{ \Gamma(\alpha, Cn^{\nu b}) \left[b-1 - \frac{k(b-c) \ln k}{(g+k) \ln(g+k)} \right] - \frac{k \ln k C^{\alpha} \nu b \ln^{\alpha \nu b-1}(g+k)}{(g+k) e^{C \ln^{\nu b}(g+k)}} \right\}$$

and if $Cn^{\nu b} < 1$,

$$S_n \propto \frac{\ln^{b-2} k}{\ln^{b-c}(g+k)} \left[b-1 - \frac{k(b-c) \ln k}{(g+k) \ln(g+k)} \right]. \quad (12)$$

Because $\ln k = \ln t + \ln \tau$ is appreciable, initially the initial change in M is given by Eq. (12), which yields the initial values of S . If $\ln \tau \gg \ln t$, it will be linear in $\ln t$, and if $b \sim 2$, S will be roughly constant initially, which appears to be the case for many spin glasses. n^{b-c} determines the difference between the initial values of S .

The factor $k/(g+k)^2$ in Eq. (11) ensures that initially it makes no contribution to S . On the other hand, it is responsible for the peak in S , and it is easy to see why this maximum occurs when $k \sim g$. It should be noted that this contribution depends on the existence of percolation clusters, and should disappear if the sample is not disordered.

COMPARISON WITH EXPERIMENT

Experimental data for S for $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_2$ obtained by Svedlindh *et al.*¹³ were compared with the predictions of the model. The fits are shown in Fig. 1. It was not possible to fit the data with the assumption that the system was below the percolation limit. The fits were scaled so that the single value calculated for $t_w = 10^3$ s, and $t = 10$ s agreed with experiment. The fraction of sites on the boundary where domain growth could start was left as an adjustable parameter. The other parameters were $d_s = 2.06$, $1/\tau = e^{6.5}$, $C = 0.0145$, and $b = 2.2$ which, if D is equal to 2.5, yields $a = 0.88$.

The value of a seems to favor Walton's model, but since the parameters are not completely independent this conclusion can only be tentative.

The change in T_g with frequency has been measured by Gunnarsson *et al.*¹⁴ for the same material. The values have been calculated from Eq. (6)

Frequency, Hz	0.005	0.05	0.5	5.1	55	510	5100	51000
T_g -measured, K	21.7	22	22.3	22.6	23	23.5	24.2	25
T_g -calculated, K	21.8	22.0	22.3	22.6	23.0	23.4	24.0	24.9

The parameters are $E = 390$ K, $V = 616$ K, $\ln \omega_0 = 30$, and $b = 2.2$. Note that these values yield the value for $1/\tau$ from the fit to S .

It is important to note that, according to the model, the peak in S is due to percolation clusters. Thus a non-disordered spin glass in which such a structure is absent should not display a peak in S . Such a system is provided by the fully frustrated pyrochlore, $\text{Y}_2\text{Mo}_2\text{O}_7$, and indeed no peak has been observed.¹⁵ However, when about 1/4 to 1/3 of the Mo is replaced by nonmagnetic Ti the peak reappears.

In conclusion, it has been shown that a simple domain growth model combined with the disordered structure of a spin glass can account for T_g and S .

AIP

Conference Proceedings from the American Institute of Physics are timely accounts of the important meetings in physics. To keep abreast of new developments, be sure to recommend them to your institution's librarian.

BRINGS THE CONFERENCE

TO YOU

394 NREL/SNL PHOTOVOLTAICS PROGRAM

REVIEW, Lakewood, CO, 18-22 November 1996 • Edited by C. E. Witt and M. Al-Jassim, *National Renewable Energy Laboratory*, and J. M. Gee, *Sandia National Laboratory* • June 1997, 1-56396-687-5, 957 pages, illustrated, cloth, 6x9, \$225.00

395 NONLINEAR AND COLLECTIVE PHENOMENA IN

BEAM PHYSICS - ICFA, Arcidosso, Italy, 2-6 September 1996 • Edited by S. Chattopadhyay, *Lawrence Berkeley National Laboratory*, M. Cornacchia, *Stanford Linear Accelerator Center*, and C. Pellegrini, *University of California, Los Angeles* • July 1997, 1-56396-668-9, 459 pages, illustrated, cloth, 6x9, \$115.00

396 NEW MODES OF PARTICLE ACCELERATION -

TECHNIQUES AND SOURCES, Santa Barbara, CA, 19-23 August 1996 • Edited by Z. Parsa, *Brookhaven National Laboratory* • August 1997, 1-56396-728-6, 208 pages, illustrated, cloth, 6x9, \$70.00

397 FUTURE HIGH ENERGY COLLIDERS

, Santa Barbara, CA, 21-25 October 1996 • Edited by Z. Parsa, *Brookhaven National Laboratory* • August 1997, 1-56396-729-4, 384 pages, illustrated, cloth, 6x9, \$110.00

398 ADVANCED ACCELERATOR CONCEPTS

, Lake Tahoe, CA, 12-18 October 1996 • Edited by S. Chattopadhyay, J. McCullough, and P. Dahl, *Lawrence Berkeley National Laboratory* • August 1997, 1-56396-697-2, 992 pages, illustrated, cloth, 6x9, \$220.00 • Book and CD-ROM packaged together.

399 THE CHANGING ROLE OF PHYSICS

DEPARTMENTS IN MODERN UNIVERSITIES:ICUPE, 31 July-2 August 1996 • Edited by E. F. Redish, *University of Maryland*, and J. S. Rigden, *American Institute of Physics* • October 1997, 1-56396-698-0, 1200 pages (2 vols.), illustrated, cloth, 6x9, \$165.00

400 FIRST LATIN AMERICAN SYMPOSIUM ON

HIGH ENERGY PHYSICS AND VII MEXICAN SCHOOL OF PARTICLES AND FIELDS, Yucatan, Mexico, 30 October-6 November 1996 • Edited by Juan Carlos D'Olivo, *ICN-UNAM*, M. Klein-Kreisler, *IF-UNAM*, and H. Mendez, *CINVESTAV* • September 1997, 1-56396-686-7, 608 pages, illustrated, cloth, 6x9, \$135.00

401 THERMOPHOTOVOLTAIC GENERATION OF

ELECTRICITY, Colorado Springs, CO, 18-21 May 1997 • Edited by J. P. Benner, and T. J. Coutts, *National Renewable Energy Laboratory* • September 1997, 1-56396-734-0, 608 pages, illustrated, cloth, 6x9, \$140.00

402 ASTROPHYSICAL IMPLICATIONS OF THE

LABORATORY STUDY OF PRESOLAR MATERIALS, 31 October-2 November 1996 • Edited by E. K. Zinner and T. J. Bernatowicz, *Washington University, St. Louis, MO* • October 1997, 1-56396-664-6, 768 pages, illustrated, cloth, 6x9, \$165.00

403 RADIO FREQUENCY POWER IN PLASMAS

, Savannah, GA, 1-3 April 1997 • Edited by P. M. Ryan, *Oak Ridge National Laboratory* and *Lockheed-Martin Energy Research Corp.*, and T. Intrator, *University of Wisconsin* • September 1997, 1-56396-709-X, 512 pages, illustrated, cloth, 6x9, \$120.00

404 FUTURE GENERATION PHOTOVOLTAIC

TECHNOLOGIES, Denver, CO 1997 • Edited by R. D. McConnell, *National Renewable Energy Laboratory* • October 1997, 1-56396-704-9, 464 pages, illustrated, cloth, 6x9, \$115.00

405 BEAM STABILITY AND NONLINEAR

DYNAMICS, Santa Barbara, CA, 3-5 December 1996 • Edited by Z. Parsa, *Brookhaven National Laboratory* • October 1997, 1-56396-731-6, 240 pages, illustrated, cloth, 6x9, \$80.00

406 LASER INTERACTION AND RELATED PLASMA

PHENOMENA • Edited by G. Miley, *University of Illinois* and E. M. Campbell, *Lawrence Livermore National Lab* • November 1997, 1-56396-696-4, 800 pages, illustrated, cloth, 6x9, \$185.00

407 DEEP INELASTIC SCATTERING AND QCD

, Chicago, Illinois, 14-18 April 1997 • Edited by J. Repond and D. Krakauer, *Argonne National Laboratory* • November 1997, 1-56396-716-2, 1088 pages, illustrated, cloth, 6x9, \$210.00

408 THE ULTRAVIOLET UNIVERSE AT LOW AND

HIGH REDSHIFT, College Park, MD, 2-4 May 1997 • Edited by W. H. Waller, M. N. Fanelli, J. E. Hollis, and A. C. Danks, *Hughes STX Corporation* and *NASA Goddard Space Flight Center, Greenbelt, MD* • November 1997, 1-56396-708-1, 544 pages, illustrated (color plates), cloth, 6x9, \$145.00

409 DENSE Z-PINCHES

, Vancouver, Canada, 28-31 May 1997 • Edited by N. Pereira, *Berkeley Research Associates*, J. Davis and P. Pulsifer, *Naval Research Lab* • December 1997, 1-56396-610-7, 656 pages, illustrated, cloth, 6x9, \$145.00

410 PROCEEDINGS OF THE FOURTH COMPTON

SYMPOSIUM: Part One: The Compton Observatory in Review - Part Two: Papers and Presentations, Williamsburg, Virginia, 27-30 April 1997 • Edited by C. D. Dermer, M. S. Strickman, and J. D. Kurfess, *Naval Research Laboratory* • December 1997, illustrated, 1760 pages (2-vol. set), cloth, 6x9 • **Part 1**: 1-56396-772-3, 592 pages, \$120.00; **Set**: 1-56396-659-X, \$300 **Note**: You may purchase the 2-vol. set or you may purchase only Part One separately.

411 APPLIED NONLINEAR DYNAMICS AND

STOCHASTIC SYSTEMS NEAR THE MILLENNIUM, University of California, San Diego, 7-11 July 1997 • Edited by J. B. Kadtko, *University of California, San Diego* and A. Bulsara, *Naval Command, Control, and Ocean Surveillance Center, San Diego* • November 1997, 1-56396-736-7, 384 pages, illustrated, cloth, 6x9, \$85.00

412 INTERSECTIONS BETWEEN PARTICLE AND

NUCLEAR PHYSICS, Big Sky Ski and Summer Resort, Big Sky, Montana, 27 May-2 June 1997 • Edited by T. W. Donnelly, *Massachusetts Institute of Technology* • December 1997, 1-56396-712-X, 1056 pages, illustrated, cloth, 6x9, \$225.00

413 TOWARDS X-RAY FREE ELECTRON LASERS

, Palazzo Feltrinelli, Gargnano, Garda Lake, Italy, 1-7 June 1997 • Edited by R. Bonifacio, *University of Milan* and W. A. Barletta, *Lawrence Berkeley National Lab* • December 1997, 1-56396-744-8, 352 pages, illustrated, cloth, 6x9, \$90.00

414 RESEARCH WORKSHOP ON TWO-DIMENSIONAL

TURBULENCE IN PLASMAS AND FLUIDS, The Australian National University (ANU), Canberra, Australia, 16 June-11 July 1997 • Edited by R. L. Dewar and R. W. Griffiths, *The Australian National University* • December 1997, 1-56396-764-2, 320 pages, illustrated, cloth, 6x9, \$90.00

415 BEYOND THE STANDARD MODEL V

, Balholm, Norway, 29 April-4 May 1997 • Edited by G. Eigen, P. Osland, and B. Stugu, *University of Bergen, Norway* • December 1997, 1-56396-735-9, 560 pages, illustrated, cloth, 6x9, \$145.00

416 SIMILARITIES AND DIFFERENCES BETWEEN

ATOMIC NUCLEI AND CLUSTERS, Tsukuba, Japan, 1-4 July 1997 • Edited by Y. Abe, *Kyoto University*, I. Arai and S. M. Lee, *University of Tsukuba*, and K. Yabana, *Niigata University* • January 1998 • 1-56396-714-6, 524 pages, illustrated, cloth, 6x9, \$124.00 (tent.)

417 SYNCHROTRON RADIATION INSTRUMENTATION

, Cornell University, Ithaca, NY, 17-20 June 1997 • Edited by E. Fontes, *Cornell University* • December 1997, 1-56396-742-1, 288 pages, illustrated, cloth, 8 1/2 x 11, \$95.00

418 STRESS INDUCED PHENOMENA IN

METALLIZATION, Tokyo, Japan, 4-6 June, 1997 • Edited by H. Okabayashi, *NEC Corporation*, S. Shingubara, *Hiroshima University*, and P. S. Ho, *University of Texas, Austin* • January 1998, 1-56396-682-4, 480 pages, illustrated, cloth, 6x9, \$130.00 (tent.)

419 TRENDS IN THEORETICAL PHYSICS

, La Plata, Argentina, 28 April-6 May 1997 • Edited by H. Falomir, R. E. Gamboa Saravi, and F. A. Schaposnik, *Universidad Nacional de la Plata* • January 1998, 1-56396-743-X, 464 pages, illustrated, cloth, 6x9, \$150.00

INSTITUTE
OF PHYSICS

To order call 516-576-2411 or write: American Institute of Physics, Marketing Department, 500 Sunnyside Boulevard, Woodbury, NY 11797. Members of AIP Member Societies are entitled to a 20% discount.

"A PHYSICIST'S OFFICE ON THE WEB"

With **PINET Plus**, you have the world of physics—and the scientists behind it—all within arm's reach. It's a research library, news center, and conference hall all in one convenient site on the World Wide Web.

**Free two-week trial—
visit today!**
<http://www.aip.org/pinet>

**e-mail: pinet@aip.org
tel.: 800-874-6383
fax: 516-349-9704**

**AMERICAN
INSTITUTE
OF PHYSICS**

PINET Plus gives you:

- **SPIN** (Searchable Physics Information Notices)—this fully searchable, browsable database is your direct link to over 750,000 abstracts from more than 80 journals, from 1985 to the present; forty-five thousand new records are added annually, and SPIN offers online ordering for full-text articles of all entries
- **Advance SPIN**—available only on **PINET Plus**, this database lets you search or browse abstracts of articles in AIP, APS, OSA and other Society journals before publication
- **Early Alert Tables of Contents**—**PINET Plus** subscribers receive exclusive, automatic early notice of the contents of AIP journals of their choice, up to four weeks in advance of publication
- **News Center**—this up-to-the-minute information service posts the latest physics-related news from research centers worldwide. It also keeps track of science-related decisions made by the U.S. Congress and other policy-making institutions
- **Membership Directories**—this online Rolodex® contains over 150,000 names and addresses from seven member societies, as well as AIP's Directory of Physics and Astronomy Staff
- **Conference Hall**—**PINET Plus** offers special-interest discussion areas. Choose from hypermail environments devoted to Applications and Industry; Astronomy, Earth, and Space Science; Funding and Grants; Employment Issues; and others

SAVE TIME AND MONEY ON CORE RESEARCH

from *The Journal of Chemical Physics* &
the Journal of Applied Physics

JCP & JAP on the Web

For decades *The Journal of Chemical Physics* and *Journal of Applied Physics* have been among the leading publications reporting vital new research in the physical sciences. Now they are also available in powerful, convenient electronic formats that can save you time and money. *JCP* and *JAP* online editions are free with a print subscription, and their CD-ROM versions can save you as much as 60% off the regular print rate.

AIP's new Online Journal Service (OJS) brings print subscribers *free* access to highly enhanced, full-text electronic versions via the World Wide Web. Available 24 hours a day, seven days a week, *JCP* Online and *JAP* Online are posted more than three weeks before their print editions. Features include: fast searches, access to the SPIN database with abstracts from over 80 physics journals, and much more.

JCP & JAP on CD

On CD-ROM these indispensable journals offer you the speed and power of electronic searching, plus a comprehensive and compact archive—imagine holding 20,000 pages of *JCP* in the palm of your hand! "CD only" subscribers can also enjoy very substantial subscription savings—see details below.

Journal of Applied Physics—1998 Rates*

24 issues, quarterly CDs ISSN 0021-8979	U.S. & Possessions	Canada, Mexico, Cent. & S. America, Caribbean	Europe, Asia, Middle East, Africa, Oceania
print †	\$240	\$325	\$510
CD-ROM	205	205	205
CD-ROM & online	240	240	240
print, CD-ROM & online	290	375	560

Journal of Chemical Physics—1998 Rates*

48 issues, quarterly CDs ISSN 0021-9606	U.S. & Possessions	Canada, Mexico, Cent. & S. America, Caribbean	Europe, Asia, Middle East, Africa, Oceania
print †	\$270	\$380	\$530
CD-ROM	230	230	230
CD-ROM & online	270	270	270
print, CD-ROM & online	320	430	580

* Rates apply to Members of AIP Member and Affiliated Societies. Call for institutional rates.

† Print includes free online access.

If you are involved in chemical or applied research in the physical sciences, you'll want to subscribe to one or both of these premier journals. The only question is, which format? For more information, call 800-344-6902 or e-mail: subs@aip.org.

Woodbury, NY 11797, USA

SIGN UP NOW! FREE with print in '98.

AIP's Online Journal Service — Creating a Whole New Research Environment

Subscribe to any AIP print journal in 1998 and you'll get access to a powerful online edition of that journal, at no additional charge. It's that easy. With the **Online Journal Service (OJS)**, you'll receive your Web version up to three weeks prior to receipt of your print copy. It's that fast.

Here are some exciting new features you'll enjoy in 1998:

- ▶ **Reference linking** — Now available on all AIP journals. Just click on an article citation and link to the referenced article's abstract in SPIN, INSPEC, and additional databases including LANL and SPIRES.
- ▶ **Online document delivery** — For journals to which you do not subscribe, download a PDF file by purchasing the article through our secure, online ordering system.
- ▶ **Full-Text HTML** — Available now for *Applied Physics Letters*. In addition to PDF and PostScript formats, you can now view articles in HTML and link to equations, tables, figures, and references. Print and download separately figures, tables, and sections of articles.
- ▶ **Article Collection** — Create your own "personal library" by storing articles of interest in a new virtual filing cabinet.

In addition, your 1998 Online Journal Service access includes — at no extra cost — a subscription to PINET Plus, your gateway to SPIN and to Advance SPIN, which give you cross-journal searching of over 80 physical science journals. PINET Plus also brings you news from national labs, searchable directories from leading science organizations, and much more.

AIP JOURNALS

- ▶ **Applied Physics Letters**
- ▶ **Chaos**
- ▶ **Computers in Physics**
(Archival Papers)
- ▶ **Journal of Applied Physics**
- ▶ **The Journal of Chemical Physics**
- ▶ **Journal of Mathematical Physics**
- ▶ **Physics of Fluids**
- ▶ **Physics of Plasmas**
- ▶ **Review of Scientific Instruments**

AIP TRANSLATION JOURNALS

- ▶ **JETP Letters**
- ▶ **Journal of Experimental and Theoretical Physics**
- ▶ **Low Temperature Physics**
- ▶ **Physics of Particles and Nuclei**
- ▶ **Semiconductors**
- ▶ **Technical Physics**
- ▶ **Technical Physics Letters**
